By an incision parallel with the inferior border of the jaw, and between it and the hyoid bone, the tongue might be drawn out sufficiently far to permit the removal of its larger portion, securing vessels as divided, and thus avoiding the dissection necessary for preliminary ligation of the lingual.

He had witnessed the removal of the tongue by the President, Prof. Sands, in which the sections were made by the galvano-caustic wire; the operation was completed without the loss of any blood, and if such an operation secured the patient against the danger of secondary hemorrhage, he would certainly regard it with favor.

THE PRESIDENT said that he could speak only of his own experience, except in a single case occurring in the practice of a colleague, in which secondary hemorrhage occurred and proved fatal. In that fatal case, however, the hemorrhage might have been due to the patient's imprudence, as she left the hospital a short time after the tongue was removed, and engaged in active exercise. He had notes of *five* cases of cancer of the tongue in which he had operated by means of the galvano-cautery. In two of these there was secondary hemorrhage. In one it occurred on the ninth day. The patient bled for several hours, and although no large vessel was opened, the loss of blood was sufficient to cause syncope, and he was found in that condition by his medical attendants. Under the use of persulphate

of iron and pressure, the hemorrhage ceased and the patient made a good recovery.

In the second case the bleeding occurred on the sixth day, and was from an artery which at the time of the operation had been divided with the knife of the galvano-cautery, this instrument having been employed to remove a portion of the diseased mass that could not be surrounded with the platinum wire. A silk ligature was applied to the bleeding artery, and it was at this point that secondary hemorrhage took place. This was successfully controlled by the reapplication of a ligature.

This case could hardly be cited as one of secondary hemorrhage following the use of the galvano-cautery wire.

He had also performed amputation of the tongue, by means of a heated wire, in a case of congenital hypertrophy. The patient recovered without accident. In cases of cancer he had not attempted to remove the tongue when the disease involved the root of the organ as far back as the line of the circumvallate papillæ; he thought the use of the wire was practicable, although difficult. But the difficulty was reduced by adopting Bryant's suggestion of thrusting pins through the tongue behind the disease, and slipping the wire over the pins, which served to keep it in position, and to prevent it from making an oblique section.

The President thought that the question as to the first method of operation in cancer of the tongue was of much interest at the present time, owing to the great success obtained by foreign surgeons in cases which we had hitherto considered unmanageable. As regards the operation of tying the lingual artery, he thought it desirable to correct a statement made by Dr. Howe, and also to refer to one or two points concerning the anatomy of the blood-vessel. Dr. Howe was in error in stating that Dr. Shrady was the first surgeon who had proposed to ligate the vessel near its origin as a preliminary measure to the removal of the tongue. Demarquay proposed tying the artery, in cases of cancer, for the purpose of cutting off the supply of blood; but he tied the artery beneath the hyoglossus muscle. The operation for tying the artery in the place where it was ligated by Dr. Shrady, and subsequently by Dr. Howe, was first performed in 1834, by Mirault. He undertook to perform it upon both sides of the neck, and found the operation extremely difficult. Failing to complete the operation upon the left side, where he was unable to find the artery, he then proceeded to ligate the vessel upon the right side, and succeeded after a long operation, in which a number of veins were tied. The operation performed by Mirault in 1834 was repeated in 1836 by Flaubert, who made a more extensive dissection than that made by Mirault, and succeeded only after dividing the hypoglossal nerve, pharyngeal veins, the external jugular, and the lingual. How often this operation had been performed, Dr. Sands was unable to say, but he thought that this method had been early abandoned, on account of the difficulty and danger attending it. At a later period, Blandin and Malgaigne proposed to tie the artery in what might be called the second surgical division of the vessel, where it lies beneath the hyoglossus muscle, a little above and parallel to the os hyoides, and behind the posterior belly of the digastric muscle. It was said that a ligature applied to this part of the artery would be placed behind the point of origin of the dorsalis linguæ.

Malgaigne performed this operation, which is the one generally performed by French surgeons, including Demarquay.

The remaining, or third division of the vessel, lies in the digastric triangle, in the space where the artery is bounded by the posterior belly of the digastricus outside, the hypoglossal nerve above, and on the inside by the fibres of the mylohyoideus muscle, under which runs the hypoglossal nerve. There the artery is much more readily found than in any other part of its course, and a sufficient number of operations have been performed to prove that it is a practical and easy procedure. The objection that, if the artery is tied in that locality, the operation does not render the tongue bloodless, is perhaps theoretical. Dr. Briddon's case would go to show that it is not, although he says that the hemorrhage was not great. But the large experience of German surgeons proves the objection to be untenable. The dorsalis linguæ artery is a very inconstant branch; usually it is small. It is inconstant in its origin, and probably often arises anterior to the point where a ligature is applied to the main artery in the digastric triangle. It is also well known that the lingual artery, in that part of its course which intervenes between its origin and the posterior border of the hyoglossus muscle, is subject to variations; sometimes it is higher than normal, arising from the facial; sometimes lower, arising from the superior thyroid; and these variations increase the difficulty of applying a ligature in this locality. Beneath the hyoglossus muscle, however, its course and position are nearly constant.

The French, for the most part, tie the artery beneath the hyoglossus muscle, as recommended by Malgaigne.

The Germans recommend that it be ligated in the digastric triangle, where it is most easily found. This operation is the one performed by Billroth.

Woelfler has collected forty-nine cases in which the operation has been performed in recent years by different surgeons. Only one proved fatal, in consequence of septicæmia.

Billroth is reported to have tied the lingual artery sixty-three times in the digastric triangle as a preliminary step to extirpation of the tongue. In ten patients the operation was performed upon both sides. Only one had secondary hemorrhage; this was readily controlled; the patient recovered. In all cases the tongue was rendered bloodless by a ligature applied to the lingual artery in the digastric triangle.

It seemed to Dr. Sands, therefore, that in view of the difficulties and the dangers encountered in applying a ligature to the posterior part of the vessel, and in view of the ease and safety with which the anterior operation can be performed, and of the protection it affords against loss of blood, it is the operation which should be imitated by us, in order to determine whether our results will be equally favorable with those obtained in Germany.

It may be interesting to describe how the operation for extirpation of the tongue, in severe cases, is performed at the Vienna Hospital.

The first step is to tie the lingual artery upon one or both sides. Then, if the submaxillary gland is diseased, it is removed; but, before its excision, the facial artery is ligated where it passes across the jaw, and also where it enters the gland. Moreover, the artery is sometimes tied when the submaxillary gland is not removed, in cases in which it is intended to remove the floor of the mouth. It is said that by ligating the facial artery the operation in the floor of the mouth can be rendered bloodless.

The incision is then extended downward and forward, when necessary for removal of enlarged cervical lymphatic glands. The tongue is then drawn forward by a vulsellum, the angles of the mouth being retracted; the mucous membrane is divided, and the tongue removed with scissors.

There is another operation, performed by Kocher, who has reported fourteen cases, with thirteen recoveries. He makes an incision along the inner margin of the sterno-cleido-mastoid muscle for several inches, and joins to it one running forward and upward to the margin of the jaw near the symphysis. The flap is dissected up, the pharyngeal walls exposed and opened, and the tongue removed by means of the galvano-cautery wire.

As a preliminary step, a tracheal tube is used. By this method very radical operations can be performed, so far as the tongue is concerned, and some of the patients have remained cured for years; but it does not seem to be so well adapted for removal of the floor of the mouth as the operation performed by Billroth and Czerny.

Dr. Charles McBurney thought that some distinction should be made with reference to the situation of the disease in the tongue when discussing the adoption of preliminary measures for preventing hemorrhage.

He thought it unnecessary to apply the acupressure safety-pins devised by Dr. Howe, because any case which would admit of the use of such an instrument would easily admit of the application of ordinary ligatures to the cut vessels.

Dr. Howe said that all he proposed to do with the pins was to compress all the vessels upon one side of the floor of the mouth, then make the necessary incision, ligate the cut vessels, and then remove the instrument and introduce and clamp it upon the other side.

The President thought it would be difficult to apply such an instrument far back where the operator would wish to apply it, if at all.

Dr. Howe had had no difficulty in introducing the pins on the cadaver, but had not used them on the living subject.

The President remarked that a similar expedient had been proposed by thrusting through the centre of the tongue a curved needle armed with a double ligature, and then constricting the tissues upon either side sufficiently to prevent hemorrhage. But it had not come into general use.

Dr. Howe said that it was Velpeau's method.

Dr. Markoe had adopted it in one case satisfactorily.

Dr. McBurney thought that such a device would be well if blood could not be prevented from going into the larynx by other methods. The use of Trendelenburg's tracheal tampon, or of a sponge-tampon, in the pharynx, was so effectual in preventing the passage of blood into the air-passages, that the only question to be considered was the quantity of blood lost, and he thought that was not to be considered in comparison with the annoyance of the preliminary use of the safety-pins and clamp.

Dr. J. C. Hutchison had operated several times for extirpation of the tongue, and, in one case, went behind the circumvallate papillæ. In all his cases he had arrested the hemorrhage by *torsion*, and secondary hemorrhage had not occurred.

### EPITHELIOMA OF THE TONGUE.

Dr. Lewis A. Stimson presented a specimen of epithelioma of the tongue, in which the disease was situated well back upon the left side, in a man sixty years of age. The tumor had been developing less than a year, and caused distress, pain, and an offensive discharge. Tracheotomy was performed as a preliminary operation, and the tongue was removed according to the method recommended by Kocher. An incision was began just behind the angle of the jaw on the affected side, and carried down parallel to the anterior border of the sterno-cleido-mastoid muscle to the hyoid bone; then forward along the bone and anterior belly of the digastric, nearly to the ramus of the jaw. The triangular flap thus formed was dissected up, the submaxillary gland exposed, the facial artery tied before it entered the gland and after its exit from it, the lingual artery tied in the digastric triangle, and the gland then removed. Two stout silk ligatures were then placed on the tip of the tongue, one upon either side of the median line, the tongue divided with scissors along the median line back to the widest part of the ulcer, and then separated for nearly the same distance from the floor of the mouth. One blade of the scissors was then thrust through the floor of the mouth into the external opening, and the soft parts divided along the ramus back toward the angle of the jaw, using the finger in the mouth as a guide to keep outside of the affected parts. After the anterior pillar had been passed, the finger of the left hand was passed into the pharynx, the constrictor pressed forward into the external wound and divided with a knife from without inward. The affected half of the tongue was then drawn out through the opening under the jaw, and its removal completed by cutting below and behind it with scissors. The cut surface was in plain sight and easy reach all the time, so that any bleeding points could be secured. As a matter of fact, there was bleeding, and that in a very slight degree, from only two points, where the incision had passed to the right of the median line. The posterior line of the incision passed about half an inch in front of the epiglottis. The surface left after removal was explored, and some suspicious tissue at a point corresponding to the tonsil removed with scissors.

On the next day the patient was sitting up in bed, and examining his mouth with a mirror. From that time the case progressed in the most favorable manner until the sixteenth day, when vague pains occurred in the calf of the leg. On the seventeenth day he had a violent chill. On the eighteenth day his temperature was 105¾° F., and on the next day 97½° F.; but on the following day it rose again, and pain occurred above the knee, but not in the knee-joint. Within two or three days a phlegmon appeared upon each elbow, and the patient died on the seventh day after the chill.

At the autopsy, *six* pyæmic abscesses were found: two in the calf, two in the knees, and two in the elbows.

Dr. Stimson was unable to account for the occurrence of the pyæmia. The man was fed up to the sixteenth day through an œsophageal tube, but on that day, for reasons in which he had no part, the use of the tube was intermitted.

A pledget of absorbent cotton in the mouth, and frequently renewed, was of great service in diminishing the discomfort of the patient. The wound at either angle was united for a distance of an inch and a half, leaving the central portion open. During the progress of the treatment the wound became nearly circular in shape, and at all times drainage was complete. There was no evidence, either during

life or at the post-mortem, of return of the disease on the surface of the sore.

The operation was very much easier to perform than he had reason to anticipate from experiments upon the cadaver.

Dr. Post remarked that Dr. Stimson's case seemed very promising until the pyæmia developed.

RESECTION OF THE PHALANGES OF THE MIDDLE FINGER.

Dr. A. C. Post presented a girl, eight years old, who in the month of December last was injured in the palmar surface of the middle finger of one hand, by a steel pen, which gave rise to inflammation that was not treated very promptly, and she suffered from swelling, pain, etc., incident, doubtless, to injury of the theca of the tendons. Finally, a free incision was made, but a portion of the flexor tendon sloughed, and when she came to him in February there was marked flexion of the first upon the second phalanx, and the joint between the second and third phalanges was immovable. He performed the operation described in the transactions of the American Medical Association for 1879, which consists in resection of the distal end of the first phalanx. Subsequently he performed a similar operation upon the distal extremity of the second phalanx, and the result was that the finger had been straightened, but its length was somewhat decreased. There was motion at the first articulation, but none at the second.

The operation consists in making an incision in the median line on the posterior surface of the finger, dividing the skin, splitting the tendon, dividing the periosteum, and removing sufficient bone to give liberty of motion and bring the finger into a straight position. He had not known any great amount of suppuration or reaction to follow the operation.

Dr. L. M. Yale presented two patients upon whom

AMPUTATION OF THE PENIS FOR EPITHELIOMA

had been performed. In one case the operation was performed by Dr. L. A. Stimson, and in the other by himself. In both cases the organ was removed close to the pubes. In both cases a large portion of the penis was involved by the disease. In Dr. Stimson's case the wound had healed completely. In his own case a few granulations remained, but they were steadily diminishing.

MYOTENOTOMY FOR CLUB-FOOT.

Dr. A. C. Post reported a second case in which he had made a free incision across the sole of the foot, dividing all resisting bands down to the bone. The patient was two and one-half years of age, was under the care of Dr. Jacobi, and had double talipes equino-varus. On the right side there was no marked rigidity, but on the left side there was great rigidity, and upon that foot he operated, and the foot was brought nearly into its normal position. There had been slight constitutional excitement after the operation, but it was subsiding, and the child was in good condition. In the case reported at the last meeting of the society, a trifling amount of sloughing of the integument at the outer end of the wound had occurred, perhaps 8 mm. in length by 6 mm. in width, but a clean surface was left, and the granulations were rapidly contracting. The foot was in a normal position, and he thought there would be no difficulty in keeping it so.

Dr. Post also exhibited a photograph of

EPITHELIOMA OF THE LOWER LIP,

which was removed with the knife two years ago in July next, and there has been no return of the disease.

Dr. Fred. Lange presented a portion of bone removed from the skull of a boy nearly four years old. The history of the case was that two boys were playing with bones taken from the wing of a turkey, and, quarrelling, one struck the other upon the head with a bone, and inflicted a slight wound, which did not attract much attention. The small wound did not heal; suppuration took place about a week after the injury, and an abscess was opened by the attending physician, and a fistula remained, from which there was a considerable discharge. The boy became pale, weak, developed constitutional symptoms, vomited readily after taking food, and, when Dr. Lange saw him, about four weeks afterward, he detected bare bone at the bottom of the wound. Tentative treatment was tried for a week with benefit, and Dr. Lange then cut down, and, after dividing the walls of the fistula, found the small piece of bone detached, which he presented. Considerable pus escaped, and he thought it had accumulated beneath the dura mater, which seemed to have been perforated by the suppurative process. The opening was at the site of the large fontanelle, and with his finger he could feel upon the left side of the wound what he thought was the falx cerebri. He was unable to find any evidence that the internal table was fractured to a greater extent than the external. He regarded the injury as due to the blow given with the bone from the turkey-wing. The case, thus far, was progressing favorably.

The President presented a specimen of

CANCER OF THE THYROID BODY,

with the following history:

John Hugg, aged forty-four years, single, weaver, Switzerland, admitted to Roosevelt Hospital, March 28, 1880; family history good; no venereal. In 1865 had a rapidly growing swelling in front of the neck, which disappeared under external application. First noticed a small tumor in front of the neck, opposite the thyroid cartilage, seven months ago. This gradually increased in size, when, four or five weeks ago, its growth became quite rapid, and a second swelling appeared on the left side of the neck. During the past two weeks, lancinating pains, dyspnœa, choking sensation, and increasing hoarseness.

*Upon admission.*—Large, dense, elastic tumor, involving the thyroid gland, extending upward to the chin and downward to the manubrium sterni. Circumference of the neck, twenty-two and one-half inches. Tumor not tender. Pulsation of the right carotid cannot be felt; that of the left external and posterior to the tumor. Complains of dyspnœa; no dysphagia; voice hissing; talking painful.

May 12th.—Tumor unchanged in size.

May 17th.—Slight attack of dyspnœa on 15th, again to-day, and died in a few minutes.

*Autopsy.*—Trachea, bronchi, and lungs congested; vocal chords approximated; liver, kidneys, and spleen congested. Large bilobed tumor of thyroid, weighing four pounds, nineteen inches in circumference. Vertical measurement of right lobe, six and one-fourth inches; of left, five inches; and of the isthmus, four inches. Both lobes extended backward to the vertebral column. The right lobe rested on the right side and in front of the trachea; the

isthmus and the left lobe to the left of the trachea. The right carotid was behind the right lobe; the left carotid external, and somewhat posterior. The cervical glands were slightly enlarged; manubrium sterni infiltrated; secondary nodule at the left sternal end of the clavicle.

The society then adjourned.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, June* 27, 1881.

DR. A. E. M. PURDY, PRESIDENT, IN THE CHAIR.

THE JAPANESE OTACOUSTIC FAN AND OTHER AIDS TO HEARING,

was the title of a paper read by DR. SAMUEL SEXTON (*vide* p. 286).

QUEBRACHO IN DYSPNŒA.

DR. O. B. DOUGLAS read the report presented by the committee from the Therapeutical Society. The remedy had been tried in thirty-two cases, embracing spasmodic asthma, with or without emphysema, cardiac dyspnœa, the dyspnœa of Bright's disease, of aneurism, of pneumonia, etc., and of those, relief to a greater or less extent was afforded in twenty-one; no relief in ten; and in one case the dyspnœa was augmented. The respiratory centre was believed to be the seat of its action, and it was regarded as not necessarily only palliative. There was no evidence that it was liable to produce disagreeable after-effects.

DR. E. R. SQUIBB, of Brooklyn, upon invitation, made a few remarks, in the course of which he suggested that in the twenty odd cases in which relief was reported as having been afforded by the use of quebracho, the remedy was used, as it seemed from the report, in conjunction with digitalis or other remedies.

Again, in the larger number of cases, the quebracho produced nausea, and in some of the cases the nausea was so marked as to prevent the further use of the drug. Nausea seemed to be a product of the administration of the medicine, and how far the nauseating effect might have given rise to the relief obtained was a question which the report had left open. In almost all forms of dyspnœa the nervous element was prominent, and in such cases very many agents relieved, and the question arose: Did the evidence show that it was entitled to special recognition as a duplicate of other agencies which were better known and of which the use was better understood? Dr. Squibb thought the testimony was not at all conclusive that quebracho was any valuable addition to the materia medica.

DR. RALPH PARSONS read a paper on

THE PRIVATE CARE OF THE INSANE.

The object of the paper was to speak of the various provisions made for the private care of the insane, and to discuss the question of the necessity for such care. Reasoning from statistics, he believed that private provision for the treatment and care of this class of cases would soon be a necessity.

He regarded the general influence of a large number of insane associates as prejudicial. The intellectual and moral faculties of the insane should be stimulated by association with the sane. The first beginning of mental improvement sometimes seemed to depend upon the removal of the patient from large wards in public institutions to family associations. Dr. Parsons believed that no great harm would ensue from a fair trial of the treatment of the insane at home, but a physician must determine the propriety of such a plan in each case.

His conclusions were:

1. Public institutions had heretofore been, and for an indefinite period in the future would be, inadequate to receive and care for the insane who needed to be removed from their own homes.

2. Asylums, on account of the necessary economy, and overcrowding, and other reasons, could not be counted as the best establishments for the treatment of the insane.

3. The smaller the number of insane persons associated with each other, the better it was for the patients.

4. The greater the ratio of sane persons associated with the insane, the better it was for the latter.

5. There were asylums, private institutions, private homes, which afforded peculiar advantages which could not be afforded by public asylums.

6. The treatment of many, if not the majority, of the insane in private houses was feasible, and had special advantages.

7. Many indigent insane persons might be satisfactorily cared for in private families.

8. Whenever more than one insane patient was under care in the same house or family, a competent physician should direct their management and care.

9. Every insane person should be under the care of a competent physician.

10. Recent cases of insanity should be treated at home, and certain chronic cases might remain at home permanently, but it was for the best interests of the majority of insane patients that provisions be made for carrying on their treatment elsewhere.

On motion by DR. SEXTON, the society tendered Dr. Parsons a vote of thanks for his interesting and valuable communication, and then adjourned.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August* 28, 1881, *to September* 3, 1881.

BYRNE, CHAS. C., Major and Surgeon. Relieved from duty at Angel Island, Cal., and assigned to duty as Post Surgeon at Benicia Arsenal and Attending Surgeon at Benicia Barracks, Cal. S. O. 142, Military Division of the Pacific and Department of California, August 23, 1881.

COUES, ELLIOTT, Capt. and Asst. Surgeon. Granted leave of absence for one month, to take effect when relieved by a medical officer, with permission to apply for three months' extension. S. O. 97, Department of Arizona, August 22, 1881.

KING, WM. H., Capt. and Asst. Surgeon. To accompany Battery I, Third Artillery, to Yorktown, Va., and remain with it until further orders. S. O. 153, Department of the East, August, 31, 1881.

WHITE, R. H., Capt. and Asst. Surgeon. Granted leave of absence for twenty days from 5th inst. S. O. 125, Department of West Point, September 2, 1881.

ADAIR, GEO. W., Capt. and Asst. Surgeon. Granted leave of absence for two months. S. O. 196, A. G. O., August 26, 1881.

STRONG, N., First Lieut. and Asst. Surgeon. To

proceed to Park City, Utah, report for temporary duty to commanding officer of the troops *en route* to Fort Thornburgh, Utah, and remain on such duty until arrival of Capt. W. C. Shannon, Asst. Surgeon U. S. Army. S. O. 84, Department of the Platte, August 29, 1881.

ARTHUR, W. H., First Lieut. and Asst. Surgeon. Granted leave of absence for one month, to take effect from date of return of Surgeon Forwood to Fort Omaha. S. O. 82, Department of the Platte, August 24, 1881.

## Medical Items and News.

* 38 Cases in Public Institutions.

A HEAD OF RYE, WITH HALF-INCH OF STRAW, DISCHARGED FROM AN ABSCESS IN THE CHEST AFTER HAVING BEEN SWALLOWED.—Dr. Howell White, of Fishkill, N. Y., writes:

Can you give me space in the pages of your valuable journal for the brief recital of the following case, which to me was one of great interest, and perhaps will be so considered by others of the profession.

On the morning of March 9, 1881, I was called to see Peter K——, a young man of seventeen or eighteen years of age, well developed, though not very robust, because of rapid growth.

I found him suffering from an acute attack of pleuritis, for which I gave him the usual remedies, also blistering the side for a considerable space.

He did reasonably well, passed through the acute stage without any material drawbacks, until the period of convalescence. This was very slow, there remaining more or less fever at night, loss of appetite, general debility, and *night-sweats*, and it was not until in April that I dismissed him, considering him cured.

About ten days from first dismissal I was again called to see him. This time I found him suffering from a slight attack of scarlatina. It following the course of scarlatina with us this year, was very light, and in a few days he was convalescent, though his general health seemed at low ebb, for which I could not account.

About this time he complained of a dull pain in his right side (the seat of the old pleuritis), which prevented him from sleeping on that side. Attending it there was cough, fever, and night-sweats. Examination revealed a large, flat swelling, perhaps fifteen inches in circumference. Palpation gave negative results—only extended dulness over the affected side.

At this time I called in consultation my father, Dr. L. H. White. He pronounced it an abscess, and probably *external*, which was the point in question (*i.e.*, abscess or empyema). He was put upon tonics, and the abscess treated as usual. Days passed, and no material change. I therefore desired a second consultation, and we together proposed Dr. Murdock, of Cold Spring. He examined the lad, and expressed the opinion that the abscess was external, though no pus could be obtained by the hypodermic needle.

At Dr. M.'s suggestion, he was ordered to bed, tonics, beef tea, punch, etc., given at regular intervals. He then began to improve, though the abscess showed no signs of discharging.

But, to make brief its history, I finally cut it, and in four places. The discharge was great and long-continued, lasting six or eight weeks.

Shortly after the opening of the abscess the lips of the wounds *everted*. This suggested the thought of necrosed bone; yet, upon probing, no bone could be discovered.

Poultices were continued, and night and morning a solution of carbolic acid was injected into the abscess.

On June 8th I received a call from Dr. Murdock at my office, as he expressed great interest in the case. I related to him what had transpired since he saw it. He exclaimed upon its long continuance, and at that time suggested the possibility of diseased bone, and I desired, should it be so, that he see the patient again with me.

From that time until June 16th I did not see the patient. On that day he came to my office, saying: 'One of my ribs is coming out.' I examined him, and, sure enough, small spicula of bone (as I then supposed, were protruding from the upper opening. They were solid, and I did not attempt their removal at that time, intending to appoint a day and invite my friend Dr. M. to assist me. I, however, introduced my probe into the wound, and *bone I could not find.*

By appointment I visited him again on June 21st. Examination showed the same state of affairs, except that the supposed bone was loose. I caught it with my fingers and removed it, and lo! I had not bone, but a *head of rye*, with one-half inch of straw attached, as perfect as on the day on which he swallowed it, which was while threshing on the 5th of March, just four days before the pleuritis developed itself, and one hundred and nine days after it had taken up its residence in his body.

I do not offer any positive solution to this medical and surgical problem, or decide which of the two roads it chose in its explorative course, contented to know that it was safely delivered from between the sixth and seventh ribs of the right side, and leave it with my brother practitioners, asking if such things often occur, and if nature is not more lenient with us mortals than we give her credit for.

A CURIOUS SPECIFIC FOR CONSUMPTION.—A well-dressed and apparently intelligent woman appeared at the dog-pound in this city the other day, and asked for the fore-quarter of a dog that had been drowned. She said that her sister had consumption, and that some one had told her the fore-quarter of a drowned dog made into a stew would cure the disease. She got the meat, and went away contented.

THE FIRST ANNUAL MEETING OF THE AMERICAN SURGICAL ASSOCIATION will be held at Oriental Hotel, Coney Hotel, September 13th, 14th, and 15th. Papers have been promised by several gentlemen.

A Peculiar Case of Hydrocephalus — Head elongated so that Presenting Part appeared to be a Normal Head.—Dr. John J. Skelly, of Potomac, Ill., writes: "The profession is prone to rush into print with every new success, and sometimes victory is proclaimed before it is won. We seldom see any brilliant mistakes recorded, but I have often thought that if some great medical luminary, with a large experience, would give us a book in which all his mistakes were plainly detailed, he would confer a great boon upon the younger members of the profession. A mistake in diagnosis in a case I was recently called to is my excuse for this writing. On April 11, 1881, I was called to attend Mrs. T——, aged twenty-eight, primipara. She had been in labor about six hours. Owing to her age and physique, I had anticipated a tedious labor. Upon examination I *thought* I discovered the head presenting in the first position, and assured the lady that 'everything was all right,' but that she might expect a tedious labor. As the case progressed she and her friends discovered that the latter proposition was strictly true. There was nothing unusual in the case that I could discover, and for six hours I thought the labor progressed naturally. The head was distending the perineum, which, though very rigid, was gradually yielding. The presenting part would project beyond the vulva during the pains, and recede again as they went off. After waiting until patience ceased to be a virtue, I dispatched a messenger after my instruments and counsel. I had given the patient fluid extract of ergot with no avail. Dr. L. C. Messner soon arrived, and after I had detailed the case and he had thoroughly examined the patient, his opinion coincided with my own, 'a very tedious case.' The child was dead, and had been for several days. We concluded to deliver with forceps. Accordingly I applied them and undertook to deliver, while Dr. M. took charge of the anæsthetic. The forceps locked all right, but I was unable to move the head. Dr. M. undertook it, The forceps slipped off, and we had to abandon any further attempt in that direction. Craniotomy was now the last resort. I perforated the scalp, when there was a gush of serum, at least half a gallon, which soaked me completely from head to foot. This is *the* interesting feature in the case. Who ever heard of a hydrocephalic presenting as a natural head in shape and consistence?

"Another peculiarity in the case is that after the serum had been evacuated and the bones of the cranium compressed so that the labor could be terminated, the head was found in the fourth instead of the first position. The child weighed fifteen pounds, minus the brain, part of the parietal bones, and the large quantity of serum. The woman has made an excellent recovery."

Medullary Cancer of the Pylorus.—Dr. Thomas C. Smith, of Washington, D. C., sends us the history of a case of the above, in which there was no pain or other symptom pointing to the disease during life. The anterior wall of the stomach was also affected, and a perforating ulcer formed at that point, which broke into an abscess in the sheath of the rectus muscle. This abscess communicated a pulsation from the abdominal aorta, which gave rise to the suspicion of the existence of an aneurism at that point.

The Effect of Hemorrhage upon the Corpuscular Richness of the Blood has recently been studied by Dr. Lyon, an American physician at Heidelberg. The experiments were made upon dogs and guinea-pigs. From 3.5 to 4.5 per cent. of the body-weight in blood was taken from the jugular vein. After the operation the red corpuscles diminish in number and continued to thus diminish for from one-half to several days, when the minimum was reached. This minimum varied with different animals. In dogs, the removal of blood to the amount of two per cent. of the body-weight would, in a few days, reduce the number of corpuscles nearly one-half.

The effect of hemorrhage upon the white corpuscles, however, was different. These increased in number for several hours, and continued in excess for several days. Hemorrhage reduced the number of red corpuscles, but increased the number of white.

The Chances of the Doctor.—There are in the United States 110 medical schools, having an annual attendance of 12,000 students, 3,000 of whom are graduated each year, and go forth to battle with life and competing M.D.'s.

This, associated with the historo-statistical fact that there are only about 600 persons to each physician now in the United States, makes appropriate the inquiry, What are we to do? Taking into consideration the fact that some of the more fortunate of the profession have more than their *pro rata* of patrons, others must have proportionally less; and while this is well enough for the former, it is, to say the least, quite sufficient to produce a lack of *patients* to the latter; and patients are just as requisite to the doctor in the battle of life as is patience to any other class of mankind.

What can be done? Those before-mentioned more fortunate of the healing tribe have, by public patronage and praise, become, so to speak, bloated bond-holders of the profession, and are not willing to close their offices and go forth to meet the honest granger and cheek him into buying a sewing-machine, or subscribing for a book, although the idea has, among the greater part of the profession, been entertained that they were going to do something of the sort. But, from the present indications, it can safely be declared no go; and now something must be done. The trouble is not that we have too many doctors, but we have got too few—people. The doctrines of Malthus were promulgated in ignorance, and are not deserving of any credence whatever; they are incompatible with the statistics and the wants of the profession.—*The Arkansaw Doctor.*

Chloral in Strychnia-Poisoning.—Dr. A. W. Parsons, of Brainerd, Minn., sends us the following facts concerning a case of strychnia-poisoning, which occurred recently in his practice:

"I was called, June 18, at 11.30 P.M., to see Mrs. J. H., who had taken into an empty stomach ten grains of strychnia crystals in one pint of water, at 11 P.M., with suicidal intent. I found her in a state of complete opisthotonos, with the convulsive twitchings characteristic of strychnia-poisoning, occurring about every two minutes, and lasting about thirty seconds each. She was conscious, and begged to be let alone, as the least jar in the room would cause a convulsion. I immediately injected into each arm sixty grains of chloral hydrate in a saturated solution; gave one drachm of pulverized ipecac; applied chloroform during convulsions, by inhalation. In about five minutes the convulsions became less frequent and violent, and in one hour and twenty minutes after the administration of the ipecac, she vomited copiously, after which the convulsions did not recur, and she rapidly recovered.

"As she was between five and six months pregnant, I expected a miscarriage; but at this time (five days after) she has had no symptom of it, and it may not occur.

"She came to me yesterday for relief from two quite promising abcesses—the result of the chloral injected. The case seems quite interesting, for it illustrates quite forcibly the power of chloral to counteract the poisonous effect of strychnine. As she did not vomit until eighty minutes after the ingestion of the strychnia, I am inclined to give the chloral and chloroform the credit for her recovery."

The Treatment of Cerebral Paralysis.—In a recent lecture (*British Medical Journal*) on the Pathology and Treatment of Cerebral Paralysis, Dr. Julius Althaus gives some useful suggestions regarding treatment. He does not take so discouraging a view of therapeutic measures as many, but thinks that few cases are met with in practice which may not be improved by judicious treatment.

In the first place, as regards actual repair of the destroyed capsule. The lecturer has had a very considerable number of cases in which there seemed to have been an actual restoration of the tissue. To secure such repair, he recommends, first, phosphorus dissolved in oil, in doses of one-thirtieth of a grain; second, the constant galvanic current sent transversely through the brain, by one electrode being placed on the right, the other on the left mastoid process, and also longitudinally by one being placed on the forehead, the other to the occiput. Such applications are to be made daily for five or ten minutes. Later on the current should be applied to the paralyzed limbs. Here faradization is also useful.

The second object in treatment is to counteract the sclerosing myelitis which is apt to follow the attack. For this we have ergot and the salts of gold and silver. Gold is given as a chloride, or better, as chloride of gold and potassium, in doses of one-eighth to one-half a grain, in pills. Silver is given as the oxide, nitrate, or phosphide, in the same doses. The three remedies may be tried in turn for a month, and that one used which seems to be most efficacious.

For promoting the absorption of the clot, iodide of potassium is useful. It must be used, as a rule, before the end of the first six weeks. It does no good in embolic softening.

Strychnia is a drug which should never be used in cerebral paralysis, according to Dr. Althaus.

The general health of the patient must be attended to. There are no watering-places which have any special therapeutic value. A moderately dry, bracing air is generally found best. High altitudes should be avoided.

Dr. Althaus estimates that twenty-five thousand persons, in England and Wales, die annually from cerebral paralysis, and that twice as many more are stricken down with it.

Syphilitic Mania. Complete Cure by the Mixed Treatment.—The following case is reported in the *Revista Frenopatica Barcelonesa*. The patient was a young Spaniard, who had served six years in the Cuban campaign. Being entrusted with the treasury of two regiments, and executing his duties with great zeal, his position was the cause of much mental fatigue. This probably brought about a cerebral congestion, which was followed by epileptiform seizures, extending over quite a space of time. Subsequently, a marked change was noticed in his disposition. Melancholia, loss of memory, and other symptoms of acute mania, together with an ambitious delirium, rendered it advisable to place him in an asylum. There it was observed that the elementary mental faculties were unaffected, but that the higher ones, reason, judgment, causality, etc, were completely deranged; association of ideas and co-ordination were lost. Acute general mania, with ambitious delirium and hallucinations, was diagnosticated, and ascribed to the common causes. Accordingly, opiates, chloral, and other nervous sedatives were exhibited, but only seemed to aggravate the malady. Finally, the use of the strait-jacket became necessary. The patient gradually failed, and became emaciated; sores appeared upon the sacrum, and death was near at hand. At this juncture it was ascertained that the man had had syphilis, and the cause of the mania was patent. Under the use of the iodide of potassium, associated with hypodermics of corrosive sublimate, the effects of treatment were evident in a few days; the fever and delirium were diminished in intensity; the autophagism ceased, and the character of the sores changed. At the end of three months, the patient was dismissed cured.

In Gastric Ulcer, to relieve the pain and irritability, and at the same time keep the bowels regular, Dr. Andrew Clark prescribes the following:

℞. Bismuth subnit.,
Magnes. carb..... āā gr. xv.
Liq. morph. hydrochloral..... ♏ xv.
Aquæ ad..... ʒ j.
M.

—*Correspondence of Canada Medical and Surgical Journal.*

The French Anti-Tobacco Society is a young, but energetic organization, which has just held an annual meeting. It now numbers one thousand members. It was founded by an army doctor, M. Decroix, who has given up his profession and dedicated his whole time and fortune to the interest of the society. The most interesting feature of the meeting was the distribution of prizes. Two old sailors received medals for giving up tobacco. A number of school-masters also received prizes for inculcating a holy horror of tobacco among their pupils.

Tobacco—A Parable.—Then shall the kingdom of Satan be likened to a grain of tobacco-seed; which, though exceedingly small, being cast into the ground, grew, and became a great plant, and spread its leaves rank and broad, so that huge and vile worms formed a habitation thereon. And it came to pass, in the course of time, that the sons of men looked upon it, and thought it beautiful to look upon, and much to be desired to make lads look big and manly. So they put forth their hands and did chew thereof. And some it made sick, and others to vomit most filthily. And it further came to pass that those who chewed it became weak and unmanly, and said "we are enslaved, and can't cease from chewing it." And the mouths of all that were enslaved became foul; and they were seized with a violent spitting; and they did spit, even in ladies' parlors, and in the house of the Lord of Hosts. And the saints of the Most High were greatly plagued thereby. And in the course of time it came also to pass that others snuffed it; and they were taken suddenly with fits, and they did sneeze with a great and mighty sneeze, insomuch that their eyes filled with tears, and they did look exceedingly silly. And yet others cunningly wrought the leaves thereof into rolls, and did set fire to one end thereof, and did suck vehe-

mently at the other end thereof, and did look very grave and calf-like; and the smoke of their torment ascended up forever and forever. And the cultivation thereof became a great and mighty business in the earth, and the merchantmen waxed rich by the commerce thereof. And it came to pass that the saints of the Most High defiled themselves therewith; even the poor, who could not buy shoes, nor bread, nor books for the little ones, spent their money for it. And the Lord was greatly displeased therewith, and said: "Wherefore this waste; and why do these little ones lack bread and shoes and books? Turn now your fields into corn and wheat; and put this evil thing far from you; and be separate, and defile not yourselves any more; and I will bless you and cause my face to shine on you." But with one accord they all exclaimed: "We cannot cease from chewing, snuffing, and puffing—we are slaves."—*Christian Secretary.*

ANTHRAX CURED BY THE INTERSTITIAL INJECTION OF CARBOLIC ACID.—In a Spanish medical journal, Dr. Muñoz publishes two cases of anthrax cured by the interstitial injection of carbolic acid. The first case was a man thirty-one years of age, of sanguine temperament and good constitution. In the upper part of the right hypochondrium he had an anthrax about the size of half an orange. Injections into the base of the tumor were practised with the following solution:

| | | |
|---|---|---|
| Carbolic acid..... | grms. | 5 |
| Alcohol..... | grms. | 10 |
| Aqua. dest..... | grms. | 100 |

After each injection (directed toward the centre of the tumor) compresses moistened with the same solution were applied. The pain diminished rapidly, and finally disappeared; the tumor decreased in size, and the temperature fell. Double injections were practised mornings and evenings for eight days, when complete cure resulted.

The second patient was a man aged forty-four years, of sanguine temperament and strong constitution. An anthrax of the size of a hen's egg appeared upon the postero-lateral aspect of the neck. The above treatment was followed out, and a cure resulted in a few days.

BRÜCKE'S THEORY OF THE CIRCULATION IN THE HEART DISPROVED.—A study of blood-pressure in the coronary arteries of the heart has lately been made by Prof. H. Newell Martin and Dr. W. T. Sedgewick, of Johns Hopkins University. These studies prove conclusively the error of Brücke's theory of the circulation in the heart. This theory, it will be remembered, is: that during the contraction of the heart the blood is driven into the aorta, pressing back the semilunar valves close against the walls. In this way the openings of the coronary arteries are stopped, and consequently no blood enters them during the heart's systole. In the diastole, however, the blood is thrown back against the closed semilunar valves, down into the sinuses of Valsalva, and then into the coronary arteries; therefore the heart is supplied with blood during the diastole, this blood-supply assisting in filling up the walls of the ventricles and dilating the heart again.

There have been a good many objections made to this theory before, but it has never been successfully disproved until now. Profs. Martin and Sedgewick, after many trials, managed to introduce a canula into the coronary artery of a dog. This canula was connected with an instrument for measuring pulsations in this artery. At the same time a similar instrument was introduced into the carotid artery, and synchronous graphic tracings were obtained. It was in this way proved that the pulsations of the two arteries were synchronous. Since, then, the pulsation in the coronary arteries occurred in systole, Brücke's theory is conclusively disproved.

THE PATHOLOGY AND TREATMENT OF THE DIARRHŒA OF PHTHISIS.—Dr. C. T. Williams has a series of articles upon this subject in the *Lancet.*

He divides the different diarrhœas of phthisis into three classes. The first includes those due simply to irritation or a catarrh of the intestines. The treatment consists simply in altering the dietary and ordering a few doses of alterative and purgative medicine, with some alkali to reduce the acidity. The second form is that arising from ulceration. The ulcers usually begin in the small intestine, near the ilio-cæcal valve; as the ulceration progresses, however, the large intestine becomes most affected. The treatment of this form requires very careful attention. It resolves itself into three sets of measures: (*a*) Rest in bed, with the administration of easily assimilable food, such as chicken-broth, beef- and veal-tea, milk-gruel, blanc-mange, always combined with *liquor pancreaticus*, after the methods described by Dr. Wm. Roberts. Koumiss also is highly recommended. (*b*) Warm applications to the abdomen, in the form of linseed poultices, turpentine stupes, or hot-water fomentations, to reduce the pain and produce derivation to the skin. In severe pain small blisters are very useful. (*c*) Internal medicines: bismuth and opium will answer in slight cases. The most powerful astringent is sulphate of copper in one-quarter or one-half grain doses. Of vegetable astringents tannic acid is the best, in four-grain doses. Indian ball is often efficacious. If the ulcerations are largely in the colon, injections or suppositories are often needed. The ordinary enemata of lead and opium will sometimes answer, but in severe cases a pint or a pint and a half of linseed-tea, combined with medicines, are needed. Linseed-tea seems to be especially efficacious. The third form of diarrhœa is due to waxy degeneration of the intestinal wall. This is hard to deal with successfully. The waxy degeneration indicates a need for phosphates of potash. The diarrhœa can only be treated, as in other diarrhœas, by the use of astringents.

THE AURAL AND LARYNGEAL HEAD MIRROR—A QUESTION OF PRIORITY.—Dr. F. Semeleder, of City of Mexico, writes: "In the MEDICAL RECORD for July 9, 1881, page 52, I find an instrument reinvented and redescribed which I am guilty of having invented and described more than twenty years ago. In speaking of the 'Aural and laryngeal head mirror,' the reinventor of which unhappily, but wisely, keeps his name a secret, I do not do so to claim priority, but just to make a wrong thing right, and I beg to refer you to my treatises, 'Die Rhinoskopie,' p. 9, Leipzig, 1862; 'Die Laryngoskopie,' p. 13, Wien, 1863; 'Rhinoscopy and Laryngoscopy,' translated by Dr. Edward T. Caswell, New York, W. Wood & Co., 1866, as well as the first edition of Josef Leiter's, of Vienna, illustrated catalogue.

TRI-STATE MEDICAL SOCIETY.—The seventh annual meeting of the Indiana, Illinois, and Kentucky Tri-State Medical Society will be held in the city of St. Louis, Mo., Tuesday, Wednesday and Thursday, October 25, 26, and 27, 1881. The profession of the "Mississippi Valley" are cordially invited to attend.

## AN AID TO THE MECHANICAL TREATMENT OF WEAK ANKLES AND INVERTED FEET.

By CHARLES F. STILLMAN, M.D.,
NEW YORK.
DELEGATE FROM THE AMERICAN MEDICAL ASSOCIATION TO FOREIGN SOCIETIES FOR 1881-82.

Although weak ankles and inverted feet comprise a class of cases constantly coming under the care of the general practitioner, they have hitherto received but little attention, owing mainly to the insufficiency of the mechanical contrivances provided for their treatment. If we examine the ligamentous structure of the ankle-joint, we observe that externally the ligaments are placed so as to allow more mobility than internally—nature evidently relying upon the inherent contractile power of the peronei muscles to hold the foot at its natural angles with the leg, and to perform all necessary eversion. The weakness or insufficiency of these muscles is of itself a sufficient cause of the deformity we are considering, even though the supports of the joint be otherwise normal; but these may also be unduly relaxed.

A tendency to turn the ankle under, to have it give way externally, to point the toes inward and downward, and an habitual stumbling, shuffling gait are the main symptoms displayed, and as every parent wishes a child to grow up with correct and graceful movements in walking, the occurrence of these defects, either singly or together, causes professional advice to be sought. There exists a feeling in the minds of the laity that it is almost useless to do so, so often has the remark been made to them by the surgeon consulted, "Let the feet alone; they will come out all right in time, as the muscle gets strong." But while the muscle is becoming restored under the influence of improved general health or local tonics, massage, etc., the deformity increases because the weight of the body must be carried by these insufficient supports, and every effort at walking upon a malplaced foot makes the deformity greater.

The physician is then driven to seek the aid of an instrument-maker to obtain a brace which will support the limb securely while the muscle is improving. The instruments which could hitherto be procured for this purpose afforded support, but allowed only a vertical motion in the ankle-joint. This feature was shared by all and is incorrect, since the normal degree of lateral movement should be permitted. If the reader will cross one thigh upon the other firmly, so as to allow no play whatever to any of the muscles above the knee, he will see that he can evert the foot in a horizontal plane about 45° by the action of the muscles *below* the knee, and if the external muscles of the leg be relaxed (not otherwise), he can invert the foot to the same degree, but its outer edge turns under.

I wish here to assert that a certain amount of lateral movement of the foot is absolutely necessary to the performance of its normal functions, and since the peronei muscles are the chief agents in the exercise of this lateral movement, any treatment directed toward the increase of power in these muscles, must provide for this lateral movement.

To allow this lateral movement to its fullest extent and yet keep the ankle supported, is the problem which has for a long time engaged the attention of surgical mechanicians.

The brace most commonly used is that represented in Fig. 1; but while this affords the ankle support on both sides, it allows no lateral movement whatever, and is therefore not satisfactory, for—with this

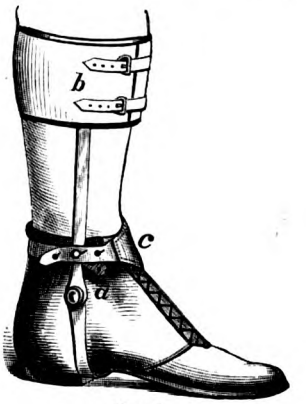

Fig. 1.

brace—if eversion be allowed at all, it is by the outward *rotation* of the entire limb on the pelvis, *and not a local eversion at the ankle.*

Now unless a deficiency of muscular power exists in the muscles of the thigh primarily, it is rare to find a case of inversion of the feet improved by an apparatus which rotates the thigh outward, as this of itself *does not* change the angle of the foot with the leg (which constitutes true inversion or eversion), and even if this condition be present, it is preferable to primarily effect eversion at the ankle, and secondarily effect a rotation of the entire limb at the pelvis, although the latter is rarely necessary, as in by far the great majority of cases of inverted feet, eversion at the ankle is alone required.

To effect eversion, a shoe is sometimes used with

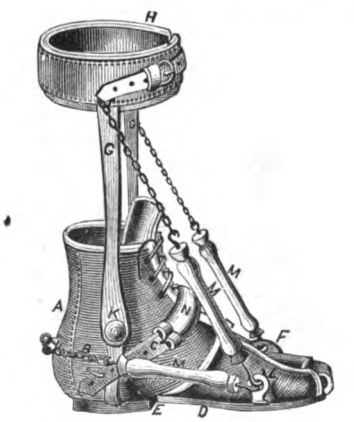

Fig. 2.

the sole divided transversely and the segments connected. In Prof. L. A. Sayre's club-foot shoe these segments are connected by a ball and socket-joint, and in Barwell's (see Fig. 3) the joint is that shown; in both, the eversion being attempted by the adjustment of appropriate rubber cords. The action of this form of apparatus, instead of being at the ankle,

is at the medio-tarsal joint, and consists in bending the anterior portion of the foot upon the posterior, and does not evert the foot as a whole, for by looking again at Figs. 2 and 3 we see that the rigid frame on either side of the heel is the same as in Fig. 1, and allows only a vertical motion at the ankle.

Another form of apparatus used for producing eversion is Prof. F. H. Hamilton's. This is shown

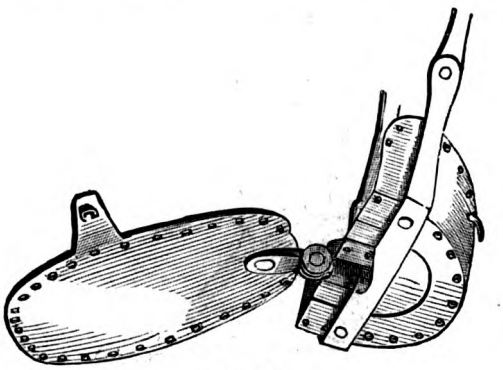

FIG. 3.

in Fig. 4, and is not practicable except on level surfaces, but is very effective, and produces a true eversion.

*Second.*—Prof. L. A. Sayre's rotating-screw (Fig. 5) is open to the objection that it allows no lateral movement at the ankle, and therefore, while effective as a rotator, is useless in producing eversion; and in Dr. N. M. Shaefer's and others the fault is the same.

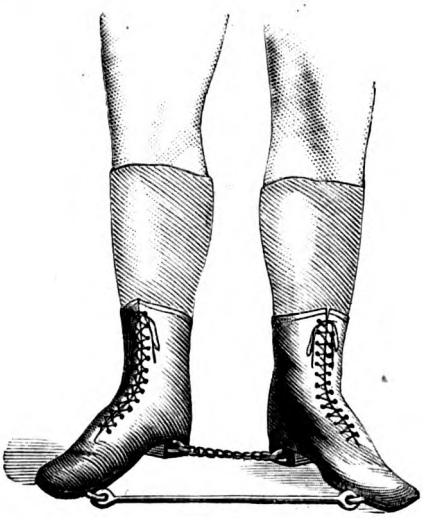

FIG. 4.

Dr. Gregory Doyle* has recently devised an apparatus which produces a constant elastic action, and, like the rotating-screw, it takes its basis of action from the pelvis, and is connected with the foot by a rigid attachment. It is an arrangement for pulling the outside of the foot upward at various angles with the leg, by means of a spiral spring, and does not admit of a true local eversion. (See Fig. 6.)

* Transactions American Medical Association for 1880–81.

This enumeration, which may serve as an introduction to the consideration of the subject proper, leads us to conclude that none of the contrivances at present in use are adapted to the physiological cure of the condition of weak ankles and inverted feet, since they do not simulate the functions of the peronei muscles, whose insufficiency causes the complaint, and do not produce eversion at the ankle-joint. These muscles have their origin above the ankle but below the knee, and their insertion below the ankle and mostly anterior to the medio-tarsal joint. Hence, to copy their action we must copy their arrangement and contrive a brace which will allow all normal motion of the foot on the leg, and still by elastic tension remedy the deformity.

I have devised an apparatus for the cure of this condition which is effective, because it is physiologi-

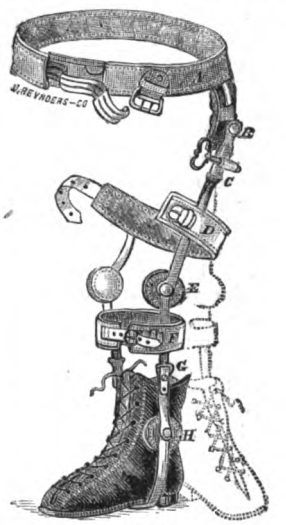

FIG. 5.

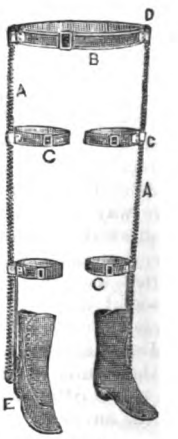

FIG. 6.

cal, and it exhibits several principles distinct from any heretofore introduced to the profession:

*First.*—It consists merely of a steel strip worn outside the leg only, so that there is nothing on the inside to interfere with the child's walking, and is extremely light and comfortable.

*Second.*—It can be worn with any shoe and is detachable at pleasure.

*Third.*—It is attached to the bottom of a shoe by a pivot in the centre of motion of the foot* (Fig. 7), thus allowing lateral motion in the ankle, a feature not possessed by any other form of apparatus.

*Fourth.*—The joint at the ankle is placed at the back of the heel, thus affording increased leverage for the action of the elastic cords and preventing the foot from going "over the centre" when the cords are in action.

*Fifth.*—The traction produced by the elastic cords corresponds to the lines of direction of the force exerted by the peronei muscles.

There are two essentials to the complete and perfect action of this brace: first, the pivot should be located at or near the centre of motion of the foot; and second, if an everting cord be used, the girth about the leg should be prevented from rotating.

The *centre of motion* (see Fig. 7) is the point where two bisecting lines meet when drawn through the foot while rotated at different angles; and, when a

* Ibid.

person stands erect, a line drawn vertically through the hip-joint should pass at or near this point; and this is the proper position in which to place an attachment between a brace and shoe, instead of against the heel, as in all other forms of apparatus.

Slipping of the leg-girth is prevented by the employment of a strip of moleskin adhesive plaster, as in Fig. 12, so placed as to have a tongue protrude in

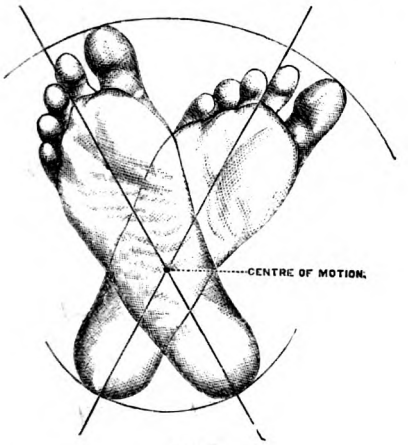

FIG. 7.

the median line posteriorly. When the brace is applied this tongue passes into the buckle of the girth, together with the tongue of the girth, effectually preventing the girth from slipping, as the buckle holds two girths, each pulling in a contrary direction; but the slight amount of this pulling does not inconvenience the wearer, owing to the distance between it and the everting cord. In the great majority of cases, however, no adhesive plaster is necessary.

Fig. 8 exhibits the pivotal attachment of the brace to the shoe when the everting cord is not attached; and Fig. 9 shows the change produced by the action of the everting cord when attached.

FIG. 8.

FIG. 9.

Fig. 10 shows the braces as they appear when applied, and their effect on the inversion. This brace is simple, unique, and efficient in all cases of weak ankles and inverted feet, and out of an experience with over fifty cases since the invention of the brace, I have yet to find one not permanently improved. The steel strip supplies rigid support, imitating the bone; the rubber cord and webbing supplies the elastic support, and the joints of the brace are so placed as to permit the utmost freedom of motion. The length, strength, and position of the elastic cords—to effect a cure in the least time—are of course left to the experience and discretion of the surgeon in charge. In weak ankles alone, without inversion, an elastic strap passing from the foot to the brace, as in Fig. 11, is to be employed. If inversion alone be present, the elastic cord is adjusted, as shown in Fig. 16, after the fixation of the girth, as shown in Figs. 14 and 15.

If both conditions be present, both cords must be employed, as in Fig. 12.

The following case I have quoted to show its effect in an extreme condition, and for its bearing upon the question of local eversion versus thigh rotation.

FIG. 10.

W. B——, aged fourteen years, Norwalk, Conn., was attacked with malignant diphtheria in November, 1876, and upon recovery the muscular system of the left limb was found of diminished size and tone. As time elapsed he became deformed—a lateral rotary curvature taking place in the back, and the pelvis becoming tilted by a sacro-lumbar* curvature until the affected limb was raised two inches from the ground, apparently that much shorter than its fellow. He was wearing a raised shoe when he came under observation, and the thigh of the affected side was

FIG. 11.

FIG. 12.

three and a half inches less than the other, the leg being two inches less. The curvatures of the back were relieved by measures to be described in a subsequent article, and the foot brought down to a level with the other (see Fig. 13). The inversion of the foot and the weakness of the ankle were extreme, and occasioned a very limping, lame gait. By the accompanying engravings—which are made from photo-

* This name, original with Dr. Stillman, is now introduced for the first time to represent tilting of the pelvis.

graphs taken July 16, by Klauser—it will be seen that the thigh of the affected side is disproportionately small (see Fig. 15), being two inches less in circumference at that time; so that I doubted the curative result to be obtained by the local evertor without accompanying it with a thigh rotator. But I found that the application of the local brace alone not only did turn the foot outward, but it also caused the entire limb to rotate normally—nature evidently demonstrating that when the foot becomes normally everted at the ankle, the proper degree of rotation of the hip will usually involuntarily follow, provided, of course, that no abnormal conditions of hip or muscles be present beyond insufficiency of muscular power.

## ANEURISM OF THE HEART.*

By E. FLETCHER INGALS, M.D.,

LECTURER ON DISEASES OF THE CHEST AND PHYSICAL DIAGNOSIS, RUSH MEDICAL HOSPITAL; PROFESSOR OF DISEASES OF THE THROAT AND CHEST, WOMAN'S MEDICAL COLLEGE, ETC.

G. H. B——, aged forty-eight; married; formerly a sailor, now United States storekeeper.

This patient came to me about four weeks ago, complaining of dyspnœa and of pain in the chest. The pain has been constant for eight months, excepting when he is at rest and for a short time after rising. It is felt beneath the sternum and over the anterior portion of the right side of the chest. It is subject to frequent exacerbations. The dyspnœa occurs at irregular intervals, and usually lasts for several hours.

Upon an inquiry into this patient's hereditary history, I find that an uncle, on his mother's side, and an aunt, on his father's side, died of consumption. His mother died suddenly, at the age of fifty, while sitting in her chair, apparently of heart disease.

Eighteen years ago, while a sailor, the patient had what was termed "African fever," at which time he vomited blood freely. About eighteen months later, while to all physical appearance in good health, though at the time troubled with a severe cough, he had a very copious hæmoptysis. A few months later he was discharged from the Navy on account of pulmonary trouble, which was pronounced consumption. His health remained poor for several months; but since that time he has been able to attend to light work, and has been in fair health.

About nine years ago he had a very severe coughing-spell, which lasted all night, but which was promptly relieved by a single dose of medicine, and did not recur.

Five years ago he had his first severe choking-spell, attended with excruciating pain in the chest; this lasted four or five hours. Subsequently, he had similar attacks, though less severe, occurring at irregular intervals for several months.

Every winter for five years he has been troubled with pain under the sternum and in the right side, excepting when perfectly quiet, with frequent acute exacerbations of the pain. Occasionally he complains of pain or numbness in the left side, shoulder, and arm, extending to the elbow—like the pain of angina pectoris. As already stated, for eight months the pain and dyspnœa have been constant when the patient is not at rest. The pain, however, subsides in a few hours after he retires, and it does not recur until some time after he rises in the morning.

As you will observe, the general appearance of this patient is that of a man in good health. There is no capillary congestion and no turgescence or pulsation of the veins of the neck or upper part of the chest. The aspect of the chest is healthy, there being neither abnormal prominence nor depression, nor loss of movement of any of its parts. But I observe marked pulsation of the right subclavian artery, and I detect a pulsating spot in the third intercostal space of the right side, near the sternum.

The radial pulse is regular, and alike on both sides, presenting no peculiarity to the touch, excepting a slightly jerking impulse. The apex-beat of the heart is in its normal position, and it is regular and as forcible as natural.

The impulse in the third intercostal space is as forcible as that of the apex.

No abnormal sounds are found on percussion over the lungs, and the cardiac dulness proper is confined to its normal area; but an area of dulness, about two inches in diameter, with its centre in the third intercostal space, extends from the normal line of cardiac dulness into the right mammary region.

Upon auscultation over this pulsating point, I hear two blowing murmurs: the first, which is the longer and louder, occurring at the same instant as the systole of the ventricles; and the second, with the ventricular diastole. These sounds may be heard, though less distinctly, in the second intercostal space of the right side, at the edge of the sternum; but they are not heard above the clavicles. They are also heard at the apex of the left ventricle, but they become very indistinct when the stethoscope is carried over the right ventricle. They are not propagated to the left of the apex, and they are not heard on the posterior part of the chest.

There is a marked shock with the first murmur over the pulsating point, but no diastolic shock is perceptible to the ear or fingers, though a faint shock is indicated by the sphygmographic trace.

FIG. 1.—Site of Abnormal Pulsation in Right Mammary Region.

We have here a group of symptoms and signs which point to several affections of the circulatory system. These are: *Dilatation of the right auricle; lesion of the aortic valves, causing obstruction and regurgitation; aneurism of one of the branches of the pulmonary artery, or of the bronchial, intercostal, or internal mammary arteries; lesions of both the mitral and aortic valves; aneurism of the heart*, springing from the right or left ventricles, or possibly a *pouch-like aneurism of the aorta.*

The pain of which this patient complains is more like that experienced in aneurism of the aorta, than like the pain which sometimes attends valvular disease of the heart; but the murmurs are of the same quality as those which are generally heard in the latter affection.

This case presents some signs which cannot be explained by the rules which apply to the ordinary diseases of the circulatory organs; in a word, it is unique so far as common experience goes, therefore a diagnosis cannot be made unless an analysis of the signs enables us to exclude all but one of the affections just named.

*Dilatation of the right auricle.*—The abnormal area of dulness, with marked pulsation in the right mammary region, at once suggests to us dilatation of the right auricle, and the murmurs suggest regurgitation through the tricuspid valves. But if this were simply an hypertrophied and dilated right auricle, its forcible pulsations would cause regurgitation of blood into the descending vena cava, with consequent turgescence and visible pulsation of the jugulars, with lividity of the face and probably an œdematous condition of the neck and upper extremities. These signs are not present.

Again, in dilatation of the auricle, the impulse would be seen and felt before the apex-beat of the heart, but in this case it follows the apex-beat.

If there were regurgitation through the tricuspid valves, the same venous signs would be found, the dyspnœa would be greater than now; the action of

* Patient presented to the West Chicago Medical Society.

the heart would be feeble and irregular, and the endocardial murmurs would be louder over the right ventricle than over the left. As these signs are not present, dilatation of the auricle and tricuspid regurgitation may be excluded.

*Lesion of the aortic valves.*—Lesions of the aortic valves, causing obstruction and regurgitation, would give murmurs similar in quality to those heard in this case, but they would not cause the increased area of dulness at the right of the sternum below the third rib; and obstructive murmurs would be heard distinctly over the aorta and its main branches, therefore these lesions may be excluded.

*Aneurism of one of the branches of the pulmonary artery.*—Aneurisms of the pulmonary artery or its branches, are so extremely uncommon, that they need hardly to be considered in this connection.

In the few cases which have been recorded, the abnormal area of dulness has never been found in this locality, while venous congestion has been marked, and dyspnœa has been much more severe than in the case before us. This affection we may also exclude.

*Aneurisms of the bronchial arteries* are very rare, and I am not aware that any have been observed, excepting as the result of breaking down of lung tissue in phthisis. In these cases the aneurisms have been small and have been located at the apices of the lungs.

An aneurism of the bronchial artery of even half the size of this abnormal area of dulness would of necessity press upon the bronchus or surrounding lung so as to greatly interfere with the respiratory murmur on the corresponding side. Such is not the case here. Furthermore, murmurs in such an aneurism would not be distinctly conducted to the apex of the heart, while absent over the right ventricle. We may, then, positively exclude aneurism of a bronchial artery.

*Aneurism of an intercostal artery.*—Such an aneurism would cause marked prominence over the tumor, and it would not be likely to reach the size indicated by this dulness. If it caused *bruits* they would not be heard at the apex when inaudible over other portions of the heart. Therefore, this lesion is excluded.

*Lesions of the mitral and aortic valves.*—Double lesions of this kind cause systolic and diastolic murmurs, the first of which is nearly always distinct at the left of the apex, and the second at the lower portion of the sternum. In this case the murmurs are not heard in these localities, and, if they were, these lesions could not account for the abnormal pulsation and dulness at the right of the sternum. Therefore, this patient cannot be suffering from valvular disease of the heart alone.

*Aneurism of the aorta.*—We have now excluded all affections which could possibly give the signs presented in this case, excepting a pouch-like aneurism of the aorta, or an aneurism of the heart.

I can find no record of a pouch-like aneurism of the aorta presenting in this locality, and, if one existed here, I should expect its murmurs to be propagated above the third ribs, and to the carotid quite as distinctly as to the apex. It might also communicate to the surface a distinct diastolic shock. These signs are not present. The sphygmographic tracings taken from the radial pulse indicate forcible action of the heart by the high and perpendicular line of ascent, and aortic regurgitation by the sudden drop in the line of descent. They are slightly different on the right and left sides, the summit of the trace from the left side indicating that the arterial tension is there maintained longer than upon the right side; but in neither of these does the trace resemble that usually found when the radial pulse is affected by an aneurism of the aorta.

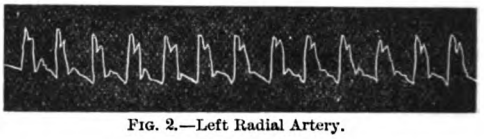

FIG. 2.—Left Radial Artery.

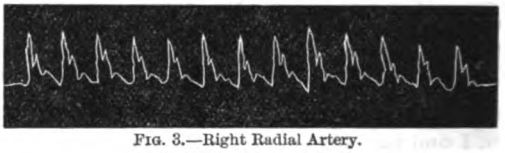

FIG. 3.—Right Radial Artery.

These facts seem to justify the exclusion of aortic aneurism, but as aneurisms of this vessel are comparatively frequent, and as they sometimes present in peculiar positions, we cannot be positive in the exclusion of this affection.

*Aneurism of the heart.*—Assuming that this is not a pouch-like aneurism of the aorta, then it must be an aneurism of the heart.

The position of the pulsation, and of the area of dulness, would make it at first appear that the right ventricle is the part involved, but the fact that the murmurs are heard distinctly over the left ventricle, and not over the right ventricle, together with the important clinical fact that an aneurism of the right side of the heart has never been found, will at once enable us to exclude a lesion of the right ventricle.

I am thus driven to the conclusion that this patient is suffering from an aneurism of the left ventricle, although recent writers state that an antemortem diagnosis of this lesion is impossible.

In the one hundred cases which have been recorded since Galeatti first described the affection in 1757, a positive diagnosis has never been made, and the true nature of the lesion has seldom been even suspected.

Hope suggests that we are justified in assuming that aneurism of the heart exists when areas of dulness and cardiac murmurs are present, which cannot be explained by the rules which apply to the diagnosis of pericardial or endocardial disease; but Laennec, Stokes, Gerhard, Walshe, Hayden, Flint, Balfour, Peacock, Fothergill, and others, pass the subject by in silence, or state that the diagnosis is impracticable.

Judging from the signs in this case, I suspect that the patient has an aneurism springing from the right side of the left ventricle, near the base of the heart, which involves the aortic orifice sufficiently to cause some regurgitation, as indicated by the sphygmographic trace. The peculiarities of the sphygmographic tracings may also be accounted for by a communication between the aneurism and the aorta (a lesion which has been found in some cases). This would explain not only the radial trace, but also the secondary curves in the trace over the aneurism; one of which would be caused by the contractions of the wall of the aneurism, and the other by contraction of the aorta.

The tumor seems to be pouch-like, and to extend beneath the right ventricle and auricle, so as to pulsate at the right of the sternum.

Aneurisms of the heart have been found most fre-

quently in males, and an analysis of the more recent records shows a tolerably equal distribution from early to advanced life.

In nearly all the recorded cases they seem to have resulted from inflammation of the walls of the heart, which has most frequently been caused by rheumatism.

In some cases direct injury or strain seems to have been the exciting cause, and it is stated that the opening of an abscess or hydatid cyst into the heart may be a cause.

In the present case the affection seems to be in some way connected with the pulmonary trouble which caused profuse hæmoptysis nearly seventeen years ago; but from the history and present signs we are unable to obtain the exact cause of that hæmoptysis, though it seems most likely to have resulted from hydatids or an abscess of the right lung.

An aneurism of the heart may occur at any part of the ventricle. Out of one hundred and five aneurisms occurring in one hundred and one cases, forty-one were found at the apex, thirty-two at the base, twenty-three at intermediate points, and nine in the septum.

These aneurisms are sometimes diffused, consisting of a simple bulging of the ventricular wall, and sometimes saccular. The latter vary from the size of a nut to that of the heart itself, and may communicate with the ventricle by either a large or small opening. At the autopsy these sacs have been found empty, or more or less filled with old or recent coagula or layers of fibrin.

Judging from external signs, the tumor in this case is distinctly saccular, and it is filled with blood which changes with each pulsation of the heart.

The walls of aneurisms of the ventricle are sometimes formed by the endocardium or the pericardium alone, and sometimes by both of these, but more commonly by these and the muscular walls of the ventricle, which have undergone fatty or fibroid degeneration; though, in some instances the muscular fibres have been found in a healthy condition.

Aneurism of the heart comes on insidiously, sometimes causing no symptoms whatever, so that no cardiac disease is suspected until sudden death occurs; but in most cases some of the ordinary symptoms of cardiac disease are present, and in a considerable number of cases the patients, besides complaining of dyspnœa, suffer from a peculiar sense of weight, with præcordial pain not unlike that attending aneurism of the aorta.

These latter symptoms have been present in the case before us, but the patient has not the ordinary symptoms of heart disease.

In the few cases which have been studied before death, the impulse of the heart has been strong or feeble about equally often, and in most of the cases endocardial murmurs have been present, due either to the aneurism or to coexisting valvular disease.

In many cases the affection has been acute and has progressed rapidly, terminating with rupture of the heart; but in a considerable number it has extended through many years.

In this patient the history and signs indicate a chronic disease. The regularity and force of the heart's pulsations, as well as the pulsations communicated to the fingers by the pulsations over the tumor, indicate that the walls of the heart, aside from the tumor, are not greatly weakened, and they also indicate considerable strength in the walls of the aneurism itself; therefore, though the prognosis is full of uncertainty, we hope that by care the patient may yet live for several years.

The treatment which has been suggested for aneurisms of this kind, is essentially the same as for valvular disease of the heart with dilatation.

In this case the physical signs of an aneurism and the character of the pain, which resembled that of aortic aneurisms, induced me to give the patient iodide of potassium. He has now taken the medicine four weeks; at first in doses of five grains four times a day; but latterly he has been taking forty grains daily.

As a result of this treatment the pain has steadily diminished, and now the patient reports that "It is not one-sixteenth part of what it was when he first came to me." In attempting to express more exactly the amount of improvement, he states that four weeks ago the pain was so severe he would not have given ten dollars for his life, but that now he is a thousand dollars better off.

## A CASE OF UTERINE MYOMA:

THIRTY-NINE INCHES IN CIRCUMFERENCE AND WEIGHING SEVENTEEN AND ONE-HALF POUNDS—REMOVED BY LAPAROTOMY.

BY PHILIP S. WALES, M.D.,

WASHINGTON, D. C.

MRS. P——, aged forty-seven years, resident of Baltimore County, Md.; married twelve years; offspring of a remarkably healthy and long-lived family; had menstruated regularly, the menopause occurring at forty-five; consulted me April last in regard to an enlargement of the abdomen. Her health, both mental and physical, was considerably impaired. She stated that about four years ago she had noticed a fulness in the lower part of the abdomen, which came on without pain or of any discernible cause, and had continued to increase up to the present moment. Now she has oppression in breathing and derangement of circulation from the encroachment of the growth upon the thorax. She cannot exercise or attend to her household duties from the protuberant and weighty abdomen.

I made a very careful examination, and found that there was a tumor extending from the pubis upward above the ensiform cartilage; it filled the pelvic and abdominal cavities fully. There was considerable effusion into the peritoneal sac. To the right of and somewhat below the umbilicus, a large fluctuating cyst was clearly definable; elsewhere the tumor was apparently solid. Adhesions were decided to be slight, if not altogether absent. The sound revealed the fact that the uterus was immovable and undoubtedly involved in the tumor. The depth of its cavity was three inches.

The patient was clamorous for relief, but I decided to send her home, and build up her general health until such time as she could bear the operation with increased chances of success. On the 5th of August I determined to operate, her general condition being as promising as could be expected by further delay. I was efficiently assisted by Drs. Hoehling and Dixon, of the Navy, Dr. Dyer, of Washington, and Dr. Maddox, of Rockville.

The operation was performed at 12.30 P.M., by making an incision in the median line five inches long in the usual manner, through which a quantity of yellowish serum and gelatinous coagula escaped.

The surface of the tumor was now clearly in view,

and inspection showed a fluctuating cyst, which was opened with a curved trocar, discharging about four ounces of pus, and a little deeper a cyst containing two or three ounces of serous fluid was evacuated. The tumor was everywhere else solid, as I introduced my hand into the pus-cavity and endeavored to break down its structure without avail. The pedicle was now sought with a view of encircling it with a ligature or an écraseur, so that the mass might be reduced and extracted piecemeal. The pelvis was so blocked up that this was impracticable. The incision was therefore enlarged, through which the entire tumor was finally extracted.

It was found to be connected with the fundus of the uterus by a large and vascular pedicle of ten centimetres in diameter; the pedicle was secured by clamp, and the mass beyond removed with the knife. The wound was closed with deep and superficial silver wire sutures after the peritoneal cavity had been thoroughly cleansed with a solution of carbolic acid.

The operation was performed under the usual antiseptic precautions, and occupied something over an hour. The patient reacted well under hypodermics of whiskey, and at 5 P.M. the temperature was 99.8°; pulse, 90; respiration, 32. Had a slight attack of vomiting; champagne, and ice at intervals.

August 6th, 3 A.M.—Temperature, 100.6°; pulse, 100; respirations, 32. 8 A.M.—Temperature, 100.4°; pulse, 100; respirations, 32. 12 M.—Temperature, 101°; pulse, 108; respirations, 30. 4 P.M.—Temperature, 101°; pulse, 110; respirations, 30. 8 P.M.—Temperature, 100.8°; pulse, 108; respirations, 36. Used catheter, and gave hypodermic of one-sixth of a grain of morphia.

August 7th, 3 A.M.—Borborygmi with occasional darting pains; has slept well since last evening. Temperature, 108.8°; pulse, 108; respirations, 18. 5.40 A.M.—Temperature, 100°; pulse, 104; respirations, 24. 9.20 A.M.—Temperature, 100°; pulse, 102. 9.30 A.M.—Temperature, 99.7°; respirations, 24. 1 P.M.—Temperature, 100.6°; pulse, 104; respirations, 28. Gave fifteen minims of tincture of opium. 4 P.M.—Temperature, 100.7°; pulse, 104; respirations, 28. Cheeks flushed; borborygmi, with occasional darting pains. Repeat tincture opium. 8 P.M.—Temperature, 100.7°; pulse, 102; respirations, 30. Flush gone from cheeks; borborygmi continue; complains of a little difficulty of respiration, which is accompanied by sighing at times. 10.45 P.M.—Hypodermic of one-sixth of a grain of morphia.

August 8th, 6 A.M.—Temperature, 101°; pulse, 102; respirations, 24. Slept well last night and feels comfortable this morning. 9.30 A.M.—Temperature, 100.4°; pulse, 100.3; respirations, 25. Is rather weaker than she has been, and complains of not feeling so well as she did up to about 8 A.M. Her expression of face is not so good as before, but she does not complain of pain. At 7 A.M. she had a little shooting pain in right iliac region. At 9.35 drew off urine and dressed wound antiseptically. At 10.30 A.M. gave tincture of opium, fifteen minims. Patient is stronger, bowels feel inclined to move. Continued the beef-tea, milk, iced champagne, according to circumstances. 2 P.M.—Complains of feeling very weak. Temperature, 100.8°; pulse, 103; respirations, 28. 4 P.M.—Temperature, 101°; pulse, 108; respirations, 28. Abdomen slightly disturbed, but not painful; had borborygmi at 4.15 P.M. Gave tincture of opii, fifteen minims. At 5.10 P.M. complains of pain in left side of abdomen; face flushed and hot. 8 P.M.—Temperature 100.8°; pulse, 108; respirations, 30. Has nausea and retching. 9 P.M.—Used catheter and arranged abdominal dressing. At 10 P.M., hypodermic of one-sixth of a grain of morphia.

August 9th, 6 A.M.—Temperature, 101.6°; pulse, 115; respirations, 28. Slept pretty well last night; had some nausea, but at present is free from that; peritonitis, 7.30 A.M. Used catheter and gave twenty-five minims tincture of opium. 10.30 A.M.—Cleaned out drainage-tube by injection of two per cent. solution of carbolic acid, and renewed the abdominal dressings. 10.40 A.M.—Temperature, 101.8°; pulse, 120; respirations, 28. Gave fifteen minims tincture of opium; complains of borborygmi. 1.30 P.M.—Temperature, 101.2°; pulse, 132; respirations, 32. Nausea; flushed face. At 4 P.M., considerable retching, with tympanites; fortified the abdominal wound with additional broad bands of adhesive plaster. 4.30 A.M.—Temperature, 100.6°; pulse, 134; respirations, 36. Is quite faint and weak, despite the supporting and stimulating means employed. 5 A.M.—Temperature, 102.2°; pulse, 140; respirations, 26. The pulse became more frequent until 9.50 A.M., when she expired. Pulse, 156; temperature, 101.8°; respirations, 41.

Inspection revealed extensive peritonitis.

The tumor removed presented the form of an oblate spheroid in shape, and weighed, three days after maceration in alcohol, eight kilogrammes, and measured, in its greater circumference, 100 centimetres. The surface is smooth, and marked by the large veins coursing over its surface, with the exception of the under side, where the pedicle was attached (ten centimetres in diameter). This side also exhibits a knob-like growth the size of an English walnut (five centimetres in diameter). On the anterior portion an abscess-cavity, irregular in outline, fifteen centimetres in diameter, the outer wall of which has a thickness of 6.3 millimetres.

Dr. Flint, of the Navy, was kind enough to make a careful microscopical examination of the tumor, and he reports that its histological characters are those of *myoma*. A large proportion of the substance of the tumor consists of non-striated muscular fibre. Sections of the hardened tissue present many of the appearances of spindle-celled sarcoma, except that the elements are less crowded and the tissue less dense; but when broken up by maceration in dilute nitric acid, the cells are found to have the outline and the elongated nucleus of smooth, muscular fibre. The tumor then would seem to have the same elementary characters as the wall of the uterus itself, and to be but an excessive and irregular development of its normal tissue.

---

ALCOHOL IN TYPHOID FEVER.—Dr. M. S. Leslie, of Lexington, says that his experience with alcohol abundantly confirms that of Dr. Ingals, as expressed in the MEDICAL RECORD of the 23d ult. In the prostrate condition of typhoid patients, nothing else so well sustains the heart and nervous system as an ounce of whiskey, or its equivalent of some other form of alcohol, given about every two hours. Great nervous exhaustion in other diseases alike indicate it. In the insomnia of typhoid fever, I find alcohol internally, in conjunction with morphine hypodermically, the best means of procuring sustained refreshing sleep.

It is only as a medicine that I would recommend its use, either by precept or practice.

# FRANKLINIC OR STATIC ELECTRICITY:

## Its Absolute and Relative Value.

By A. D. ROCKWELL, A.M., M.D.,

ELECTRO-THERAPEUTIST TO THE NEW YORK STATE WOMAN'S HOSPITAL, ETC.

The *absolute* value of franklinic electricity as a therapeutic agent is, without question, very great. Its *relative* value cannot be estimated with the same readiness, since conclusions on this point render it necessary to compare its effects with those of dynamic electricity.

Any arguments, therefore, in the direction of showing that franklinic electricity has greater claims upon us as a remedy than has been generally believed, must of necessity be quite valueless, unless they are based upon a thorough use of the two forms of dynamic electricity; especially by the methods of general faradization and central galvanization. The difficulty of obtaining reliable and exact information in regard to this matter will undoubtedly be due to the fact that, in the future as in the past, clinical reports will be too often given by those who have had no systematized or adequate experience in the use of dynamic electricity.

Sedative and tonic effects of a very interesting character are undoubtedly obtained through franklinization; but these effects are equal neither in variety nor degree to those that follow the careful and thorough use of dynamic electricity by the methods mentioned above. None the less, however, do we hail the recent revival of this neglected department of electro-therapeutics, not only because in certain conditions it may possess some advantages, but because, through peculiar idiosyncracies, it is occasionally better borne than the other forms.

It must not be forgotten, however, that, as a rule, general faradization is far more agreeable than the treatment by sparks, however carefully given. Of all the approved methods of using electricity, franklinization has perhaps the advantage of requiring the least skill and experience in its administration, and the disadvantage of necessitating apparatus that is cumbersome, expensive, and not in the same degree reliable as the instruments for the generation of dynamic electricity.

A still further advantage lies in the fact that little if any disrobing is necessary, since the drawing of sparks and the general stimulation of the surface is accomplished through ordinary clothing. Another important reason for the use of franklinic electricity, and one which to my gratification I have thoroughly tested, is its occasional value in supplementing, and, if it may be so stated, of reinforcing the constitutional tonic effects or general faradization.

It is one of the familiar things in medicine, that a remedy which at first acts most effectually, may, after a time, cease to have the desired effect. If, now, we substitute a remedy of the same class, even though it be inferior, further benefit often follows, and upon returning to the original treatment it acts with renewed vigor. The same principle holds good in regard to the dynamic and franklinic forms of electricity.

Occasionally cases of nervous exhaustion, as well as other forms of disease, after improving up to a certain point under the influences of galvanism or faradism, hang fire, as it were; but, by submitting the patient to the action of franklinization, a new impulse seems to be given. In this way—one treatment supplementing and reinforcing the other—results are obtained far more satisfactory than could possibly follow the exclusive use of general or localized faradization—central galvanization or franklinization.

A word in regard to the Holtz machine, the best apparatus for the generation of franklinic electricity for medical purposes. This contrivance, although a great advance upon the old-fashioned cylinder machine, still proves inoperative, during most of the summer months at least, and frequently fails at a critical moment during the cold of winter.

Vigoroux has recently been experimenting in this direction in Paris, where it has been found that if the ordinary Holtz apparatus is covered with a glass case, in which is placed a quantity of chloride of lime and sulphuric acid, by which all moisture is absorbed, electricity can be generated with more or less readiness in all kinds of weather. The apparatus with this contrivance, as manufactured by J. & H. Berge, of this city, is represented in Fig. 1.

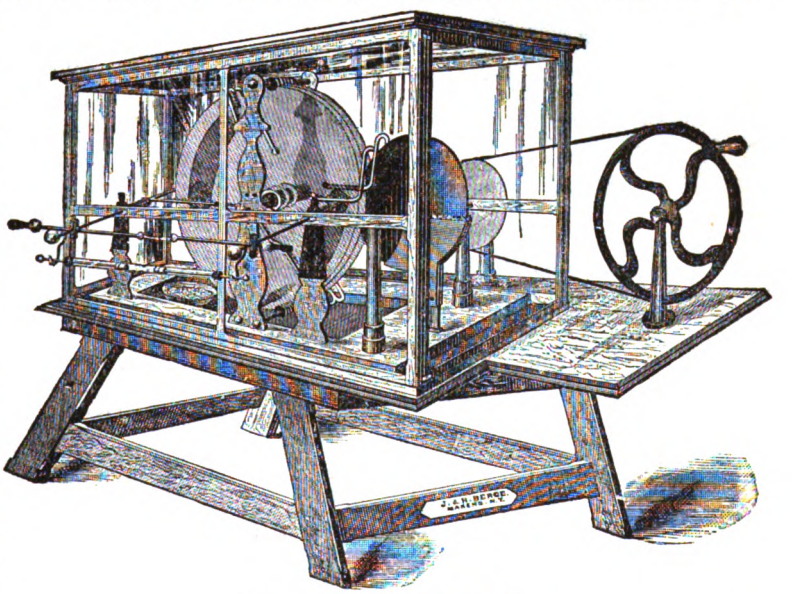

Fig. 1.—Apparatus for Franklinization.

Fig. 2 represents a patient in a state of insulation, and the operator in the act of drawing sparks from his body.

Recently, in an apparatus constructed by the same firm, this annoying inconsistency has been to a great degree removed by a simpler and much less expensive device. In the place of the ordinary comb-points, bunches of tinsel are substituted, the friction from which, added to the inductive properties of the machine, insures an almost perfect result.

Dr. Bartholow* describes a Holtz machine with a so-called Toepler modification, for which he claims

* Medical Record, May 7, 1881.

quite uniform results. Both the tinsel and Toepler attachment, however, although doing excellent work, fail occasionally, and those who desire a perfectly constant apparatus will do well to order the glass case cover, as illustrated in the cut. The plates should not be too small. The kind that answers

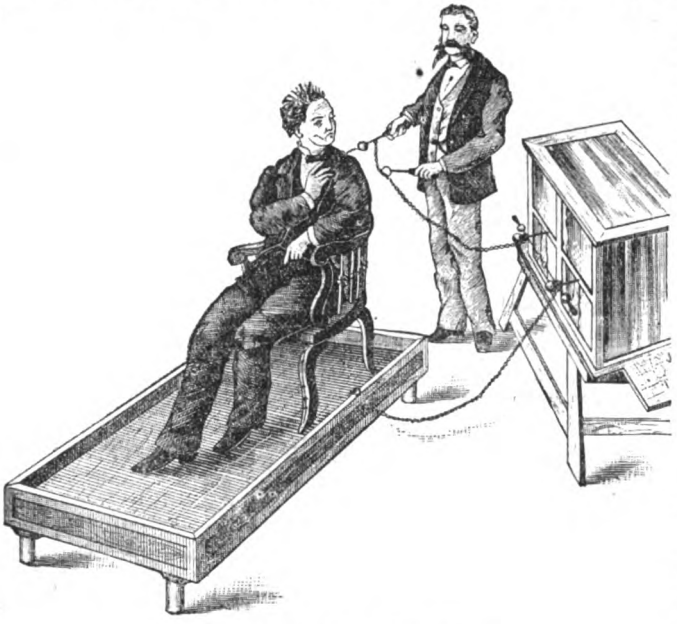

FIG. 2.—Electrization by Sparks.

every purpose is the *double* Holtz, consisting of four plates, two stationary and two revolving, the latter being about twenty inches in diameter. The electrodes consist mainly of brass balls of various sizes (mounted on glass handles held by the operator),

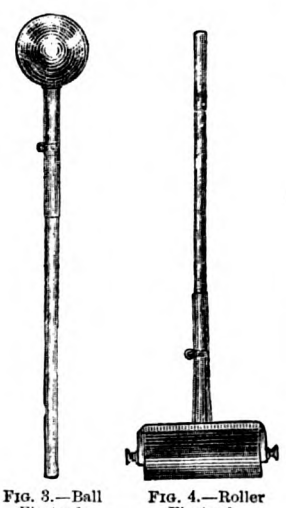

FIG. 3.—Ball Electrode.

FIG. 4.—Roller Electrode.

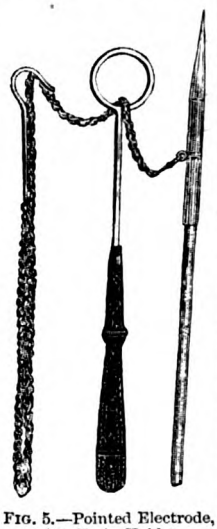

FIG. 5.—Pointed Electrode, with Chain Holder.

and connected by a brass chain with the ground, or, better still, with the nearest gas- or water-pipe.

Fig. 3 illustrates this form of electrode.

As a substitute for general faradization, although by no means so effective, and far less agreeable, the metallic roller—Fig. 4—may be used. It acts reflexly, and also directly excites the cutaneous nerves. When the roller is used upon the bare skin, the conduction is so perfect that no sensation is appreciated. It is only when the clothing intervenes, acting possibly as a sort of Leyden-jar, that the peculiar pricking sensation is observed. It is needless to say that, to obtain the best therapeutic effects of the roller, it should be applied over the clothing. The electric wind so called, following the use of the pointed electrode—Fig. 5—is due to the agitation of the air between it and the person treated. The discharge is silent and the effects agreeable and refreshing.

The static induction current,* which is obtained from a franklinic apparatus, has been suggested as a substitute for faradic electricity.

It is claimed for this current that it produces maximum muscular contractions with a minimum amount of pain, and that the response is quicker than that from the faradic current. As for the first claim it is difficult to see how it can be determined, since the faradic current from the single coil apparatus especially, need seldom, if ever, call forth pain in the production of muscular contractions.

As to the alleged greater quickness of response, I have not been able to discover that the new current has any advantage in this way.

The change in the apparatus for the production of this current is quickly and easily effected, and for the purposes of localized electrization, it is useful. For general faradization, however, it is quite unsuitable, and inferior even to the poorest forms of faradic batteries that are advertised so widely and sold in such great numbers. To determine the exact therapeutic status of franklinic electricity, we need still to experiment and observe.

A considerable experience, however, in its use would lead me to thus formulate what I believe to be the approximate truth in regard to this matter.

*First.*—As previously stated, tonic and sedative effects of a very interesting and positive nature, can be obtained from franklinization, either by insulation or sparks, but these effects are equal neither in variety nor degree, taking the cases as we find them, to those following the use of dynamic electricity, if used thoroughly and conscientiously by the methods of general faradization and central galvanization.

As supplementing these methods, however, when in protracted cases they seem to have lost their effect, we have abundant testimony of its value.

*Second.*—It has been long known that many temperaments and conditions of disease will bear faradization or galvanization readily, while shrinking from electrization from sparks. More recent experience, however, has convinced me that the reversed condition of affairs occasionally prevails.

At the present time I have under my care two female patients who are suffering from analogous affections. One regards general faradization as exceedingly agreeable and as benefited by it, but shrinks from the treatment by sparks, by the roller (general

* This current was first described by Dr. Morton in the New York MEDICAL RECORD, April 2, 1881, and by Dr. Bartholow in his Manual of Medical Electricity, recently published.

franklinization), and even by the milder method of insulation. The other much prefers the most positive treatment by franklinization.

*Third.*—In the enlarged joints of subacute and chronic rheumatism the treatment by sparks is frequently more efficacious than either faradization or galvanization. In acute articular rheumatism, however, the descending faradic current affords the greater relief.

*Fourth.*—In old contractures, and possibly in cutaneous anæsthesia, franklinization may possibly possess some advantages.

*Fifth.*—In electro-diagnosis franklinic electricity is of limited value; those quantitative and qualitative changes, which are so important as indicating structural degeneration, being produced only through the action of the two forms of dynamic electricity. In electro-surgery also it is manifestly of but little value.

*Sixth.*—Franklinic electricity will occasionally relieve pain where the dynamic fails, and in general is undoubtedly superior for this purpose to the faradic current alone; but, as compared with both the galvanic and faradic currents, no advantage has nor probably can be demonstrated. In the treatment of neuralgia I have found its chief value to lie in those cases which are associated with a hysterical condition, and in the so-called pseudo neuralgias, which are simply forms of pain occupying certain areas, and running *seemingly* in the direction of certain nerves. Such conditions are sometimes called hysterical hyperæsthesia, where it is observed that firm and prolonged pressure frequently affords marked relief, while pressure superficially applied increases the distress. It is in these cases *also* that the faradic current is most and the galvanic least effective.

*General suggestion.*—In summer, and sometimes in winter, the atmosphere will occasionally be in such a condition that the Holtz apparatus, with its tinsel or Toepler attachment, will work with comparative feebleness. Even when enclosed in a case it will, during some of the warm, damp days of summer, act with much less than its usual power. At these times the chain or bar from the instrument, instead of connecting directly with the insulating stool, should be held in the hands of the patient thus insulated. In this way a better action is secured. It should be noted also that there is great variation in susceptibility of the different parts of the body to any form of electrization. To administer general faradization properly, it is essential that the operator should submit himself repeatedly to its effects, so that, through personal experience, he may have knowledge of these varying degrees of susceptibility.

The same rule must be observed in the treatment by franklinization, otherwise the patient will be liable to suffer unnecessarily.

In the use of franklinic electricity it is especially necessary to be thus prepared, since it is quite impossible to graduate the effect of sparks drawn from the body as accurately as we regulate the action of current electricity.

---

Traumatic Tetanus Successfully Treated with Very Large Doses of Calabar Bean.—A case of this kind is reported by Dr. J. C. Minor (New York *Medical Times*). In less than twenty-four hours, during the height of the disease, one hundred and four grains of the extract were given. This is the largest amount ever given—certainly by a homœopath, to which school Dr. Minor gives allegiance.

# Progress of Medical Science.

Hernia of the Ovary, simulating Strangulated Inguinal Hernia—Extirpation—Recovery.—The patient, a hysterical woman of forty-eight years of age, was born with a small, hard lump in the left inguinal region. The tumor had never been painful, nor did it ever enlarge during menstruation; it was irreducible. A truss had been worn constantly. A month before admission to the hospital the lump began to enlarge, and at the time of entrance she was suffering from gastro-intestinal catarrh as the result of the free administration of purgatives. The swelling itself was moderately painful, felt like a piece of omentum, and the superincumbent cutis was decidedly reddened. Under the impression that he was dealing with a congenital, irreducible and inflamed inguinal epiplocele, Raffo at first resorted to symptomatic treatment merely. Symptoms of strangulation suddenly manifested themselves, the previously present meteorism rapidly increased, and the pulse became small. Believing that a small loop of intestine was caught beneath the prolapsed omentum, Raffo proceeded at once to perform herniotomy. Meeting with a tensely distended sac, believed to be the hernial sac, an incision was made which gave vent to a quantity of sticky fluid. The cyst was found continuous with a solid, elongated body in the inguinal canal which proved to be the left ovary, and was excised after enlarging the incision and opening the peritoneum. The body of the uterus was felt almost in apposition to the internal inguinal opening. A drainage tube was inserted, Lister's dressing applied, and the symptoms of incarceration rapidly passed off. After the wound healed, the hysterical symptoms became much less marked.—*Lo Sperimentale*, 1881, No. 1; *Centralblatt für Chirurgie*, May 14, 1881.

The Value of Inhalations of Medicinal Agents.—Dr. J. Gottstein, of Breslau, has, in a practice of twenty years, made repeated trials with inhalations of medicated fluids in the treatment of affections of the respiratory organs, but has at length become convinced of their uselessness in most cases. The method is a favorite one with busy general practitioners, because of its apparent simplicity and easy applicability, but it is harmful in so far as it tends to displace more effective topical treatment with the sponge, pencil, syringe, and insufflator. The author admits the benefits apparently due to inhalations in croup, acute laryngitis, etc., but attributes the good results entirely to the solvent properties of the inhaled steam.

The only conditions in which he believes inhalations to be of value, are:

*First.*—Cases of acute laryngitis and bronchitis with scanty secretion, where patients are tormented by a sense of dryness in the throat, and consequent annoying desire to cough. These may be allayed by frequent inhalations of steam (either pure, or charged with chloride of sodium, chlorate of potash, or similar solvents).

*Second.*—Cases of laryngitis where the secretion has a tendency to become inspissated and form crusts.

*Third.*—In cases of laryngeal, tracheal, or bronchial disease where expectoration is rendered difficult by the tenacity of the secretion, or by any other mechanical causes.—*Betz's Memorabilien*, June 10, 1881.

# THE MEDICAL RECORD:

## A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 17, 1881.

## SOCIAL SCIENCE THEMES.

It is only a truism to say that medical science is deeply interwoven with the interests of humanity. Aristotle said it some two thousand years ago, while if any one impugns such authority he can be referred to Descartes, who lived later, and put the matter more strongly still. It follows easily, then, that an association which makes a special study of society as a whole, should call to their aid those whose life is spent in studying the units.

At the recent meeting of the American Social Science Association at Saratoga, there were no better papers than those offered by physicians. This, we might add, however, is not extreme praise, for the association in question has not yet attained the highest rank and dignity as a scientific body. But the medical papers at least deserve careful attention.

In the Department of Health, Dr. Walter Channing, the Chairman, delivered a discourse upon "The Care of Insane Criminals and Inebriates." As regards the treatment of the insane, the point that he made was, that they needed moral treatment as well as physical. No system of psychology, he said, had as yet demonstrated the whole nature of insanity. It is a one-sided view which regards the lunatic as being like a man with a broken leg. He requires moral and social, as well as physical care. The old-fashioned method of putting the good and the bad, the rich and poor, the ignorant and cultured together, was a vicious one. Especial attention should be paid to the social relations of the insane. The need of separate asylums for insane criminals was very urgent. Such asylums had as yet been supplied in but few States; but there they had already done much good.

Some excellent suggestions were made in regard to the management of inebriates. The care and reformation of drunkards, the speaker thought, was one of the most vital questions of the day. In the inebriate we have a combination of the lunatic, the moral imbecile, and often of the criminal. There are more inebriates in the country than lunatics. They are more dangerous and injurious to the welfare of society. Though legally the inebriate is a responsible person, yet, so far as the care of himself is concerned, he is the most irresponsible of beings. But we have this advantage as regards him: We know the cause of his condition, and we know the method of cure, when cure is possible. Dr. Channing recommends the commitment of inebriates to reformatories by the courts. These reformatories should be unlike any institutions now in the country. The inmates should be graded according to behavior; their treatment should consist of work of various kinds; at least three years' residence should be required—and the speaker dwelt with particular emphasis upon the importance of this element of time.

Coming in opportunely with the foregoing paper, was one by Dr. Mary Putnam-Jacobi upon "The Moral Treatment of Insanity." Especially interesting were the author's remarks upon the education of children who have neuropathic tendencies; how, in other words, to prevent insanity by properly training those in whom its future development is to be feared. The three leading indications of an unstable mental condition are: An incapacity to grasp ideas, a weakness of the will, and a pronounced, though often unconscious, egotism. These traits are to be eradicated or toned down by a judicious watchfulness. The suggestions made by the author of the paper showed the sensible application of her extensive knowledge and acute observation. They could be well applied to the education of children who are not neuropathic.

A paper by Dr. Emily Pope, on "The Practice of Medicine by Women in the United States," introduced a less interesting topic. Dr. Pope, however, presented some statistics upon this subject which were evidently gathered with much care. They furnish an excellent supplement to similar figures read at the commencement of the Women's Medical College of Philadelphia, last spring. According to the author of the paper there are in the United States 470 women physicians, of whom 390 are engaged in active practice. These women are in twenty-six States, New York, Massachusetts, and Pennsylvania having the largest proportion. Of those heard from, 75 per cent. were single when they began the study, 19 per cent. were married, and 6 per cent. widows; 341 practise regular medicine, 13 homœopathy. 77 report that they supported themselves from the beginning of their practice, 34 in less than 1 year, 57 after the first year, 34 in 2 years, 14 in 3 years, 10 in various periods over 3 years; only 11 are left who can fairly be said to have practised over 2

years without supporting themselves; 269 are in general practice, 45 make a specialty of female diseases, and 4 of ophthalmology.

These statistics show a larger per cent. of women engaged in general practice than is usually supposed. Other investigations have led to the conclusion that nearly one-half follow some specialty, generally that of gynecology, obstetrics, or diseases of children. As regards health, it was stated that of 130 who have practised less than 5 years, 76 report health good, 51 health improved, 3 health not good.

On the whole, the figures lead to the conclusion that the practice of medicine has been successfully followed by these four hundred American women. It has furnished them a livelihood, and has neither impaired their health nor interfered markedly with their social relations. The great question, of course, as to their skill as practitioners, or their usefulness to society, cannot be settled by figures. That women can practise medicine with success, however, is established, and this fact gives her the right to do it. The great difficulty, admitted by Dr. Putnam-Jacobi in an admirable address upon the medical education of women, lies in the fact that women are partly inclined and partly compelled to fall into a special practice. But it is essential for good specialists that they first have a sound knowledge of all the different branches of medicine. This it is almost impossible for women to obtain at present, either in hospitals or in private practice.

In the department of education, the topic of "The Development of Infant Life" was brought up for discussion. This subject, which we referred to editorially some time ago, is now being investigated by the Secretary of the Educational Section. Hundreds of educated women, we are informed, are occupied in collecting facts upon this little known branch of psychology. The Secretary was not yet ready, however, to make any systematic report upon the matter. A letter from Mr. Charles Darwin was read, in which that eminent naturalist gave many useful suggestions toward carrying out the work.

The last day of the session was largely occupied with papers and discussions upon "Tenement-Houses, and the Moral and Physical Evils they Induce." The success of co-operative building associations in remedying this evil was referred to, but discussion showed that they had, as a rule, failed in other places than Philadelphia.

The President, in declaring the session finally closed, alluded to the fact that the attendance had been larger than at any previous year.

---

### THE STATE BOARD OF HEALTH AND HUNTER'S POINT.

The persistence of the Hunter's Point stenches has raised an interesting question as to how much the State Board of Health can effect in the way of removing nuisances. This Board, in accordance with requests, made a thorough examination, not long ago, of the causes of the stenches coming from Hunter's Point. They found that the smells were produced by the dozen oil refineries which are situated on Newtown Creek. From most of these establishments the washings, containing sludge acid, are poured out into the creek. At low tide, the shores, piers, and stones are covered with the sludge tar and sludge acid, which give off the offensive odors so evident in New York.

The State Board of Health, therefore, passed a resolution, as they were authorized to do by law, requesting the Governor to "close at once all the oil refineries and other establishments on or near Newtown Creek that permit sludge acid, sludge tar, or any other offensive refuse to run into the creek or upon the neighboring grounds, or allow offensive odors to escape, until such time as, in the opinion of the committee, such improvements shall have been made in the factories as will in future prevent such offensive discharges and odors."

In response to this, the Governor issued a proclamation in due form, calling for an abatement of the nuisances in question.

The press has seconded most heartily the efforts of the State Board, but as yet the matter is at a standstill. No active steps to close the offensive manufactories have been taken, and it remains to be seen whether the Board of Health is to have an authority which is only nominal where the interests of profitable corporations are concerned. There is considerable confidence expressed by some of its members that it will ultimately succeed; and some help is likely to be afforded it by a society which has recently been organized "for the suppression of Hunter's Point nuisances." This society will devote its energies to sustaining the action of the Health Board, and securing the execution of the law under which that body was created.

---

### NOTES ON THE PRESIDENT'S CASE.

The removal to Long Branch, and perhaps we should add the appointment of a day of prayer, and the reduction of the medical staff, seem to have produced a slightly favorable change in the President. The press reports show that five out of the seven days since last writing have been marked by an improvement in his condition.

The reduction of the medical staff was a wise move, indicating as it did no lack of confidence in the gentlemen who have been dismissed, but rather an improvement in the condition of the patient. It was a necessity to the physicians, as well as to the President, that there should be several in attendance at first. No one man could have endured the tremendous responsibility of the case or have

kept up under the merciless torrent of criticism that would have been poured upon him. And after all the patient was let off quite easily. In olden times the potentates of the earth believed in the efficacy of numbers, and Charles II. died *secundum artem*, after having been treated by sixteen of the most eminent medical men in the land.

One of the gentlemen discharged, Dr. Woodward, though without a peer in his department, is rather more famed for scientific knowledge than practical skill. Dr. Barnes also has not been known to the profession by any active work for some time.

We are obliged to confess to a feeling of thanksgiving, which is especially active and profound, that the President has shown the good sense to deliver himself from that—doubtless very estimable—female homœopathic physician, Mrs. Doctor Edson. She is reported to have been Mrs. Garfield's family doctress, and was retained as nurse in the present case presumably because the President did not wish to hurt the feelings of his wife. Mrs. Garfield's devotion has been great and her gruel unexceptionable, but she can hardly expect the mass of her loyal subjects to admire entirely a character which endorses female homœopathy.

The reports concerning the President show, as we write, some increase in strength upon that of a week ago. The temperature has been lower. On two days the afternoon bulletin recorded it as normal. The pulse has kept quite steadily at 100. The respiration rose on one day to 20, but for the rest of the time, has shown no elevation. There has been, however, a slight fever every day. This fever, the rapid pulse, and the great weakness of the patient appear to be the chief bad symptoms in the case.

The public was much alarmed on the 10th and 11th instants by an increase of fever and a threatened relapse. This brought out the hitherto unannounced fact that the patient had been coughing more or less for three weeks, and was suffering from a bronchial catarrh. It was also stated that a slight area of dulness had been detected at the lower part of the right lung. It was a question for some time whether this was not an evidence of hypostatic congestion, and, perhaps, a beginning of bronchopneumonia. It is the impression at date, however, that the dulness is due to the liver, and that the cough was caused by a catarrh. The record of the respiration and pulse certainly confirms such a view.

Favorable reports have been given in regard to the wound. The catheter passes in a shorter distance, and it is believed that healing from the bottom has really begun. This, together with the fact that the incisions into the parotid gland have healed, are most favorable signs, as indicating that the vital powers of the system are not at a low ebb.

The question of the position of the ball has been discoursed upon by Dr. Hamilton, whose usual granitic reticence is sometimes forced to yield to the importunities of the unspeakable reporter. He says:

"We think we have discovered the situation of the ball, but this discovery (if it is such) was made as far back as July 24th. We have never lost sight of the ball from that day to this; it lies under the psoas muscle in the right iliac fossa, where it can be distinctly felt as a hard substance. Pressure over this point is not painful.

The suppuration of the parotid gland resulted in a fistulous opening by which pus passed into the mouth. This, however, is nearly or entirely healed. In regard to the medical bulletins, there continues to be but one feeling, which is that they are incomplete and unsatisfactory. In none of them has the existence of the cough, the bronchitis, or the suspicious area over the right lung yet been announced. Nor do we learn by them anything exact as to the character of the wound. Both the general public and the medical profession have had to depend upon the admirable dispatches of Secretary Blaine for the facts upon which to base an opinion of the President's real condition.

It has not been revealed who is the author of these much-studied bulletins, but surely they could be made into better English, not quite so insanely optimistic, and not quite so uniformly obfuscated with unmeaning generalities.

---

### THE AMERICAN SURGICAL SOCIETY.

This society held its first annual meeting at Coney Island during the past week. Owing partly to the fact that many leading surgeons had not yet returned from Europe, the attendance was not large. Still there were present representative surgeons from this city, Brooklyn, Philadelphia, and from the South and West. A number of excellent papers were read, while the discussions following them were carried on with much spirit.

The attempted assassination of the President, and his consequent long illness, has aroused a special interest in surgery, among the laity as well as medical men. Consequently the proceedings of the present meeting received much attention.

It is understood that one of the objects aimed at in creating this organization was to make more marked the distinction between surgery and general medicine; in other words to develop the former into more of a specialty. It was hoped, too, that by forming a national surgical society the prestige of a greater solidarity could be given. The publication of an annual volume of transactions is intended in the future, but none will be issued for the present year.

# International Medical Congress.

*Held in London, England, August 3 to 9, 1881.*

(Special Report for THE MEDICAL RECORD.)

## MEETINGS OF THE SECTIONS.

### SECTION ON OBSTETRICS.

#### TARNIER'S FORCEPS.

On the morning of the first working meeting of the Section, the discussion was opened by Professor Tarnier in an eloquent address on the forceps. He briefly traced the history of the perineal curve of the ordinary instrument, and objected to it for two reasons: 1st, traction could not be made in the axis of the pelvis, and might injure the pelvic walls; 2d, the force being applied too far from the centre of the fetal head, the instrument was turned into a lever, which might again injure the pelvis whenever a movement was made to one side or the other. Professor Tarnier exhibited his own forceps, together with the latest improvements made in it, and claimed that by it traction could be made in the axis of the pelvis, traction could be applied to the centre of the fetal head, that the head could move as freely when grasped by the forceps as it could in natural labor; that in this forceps the operator had an indication which pointed out the movements of the fetal head, and thus obtained a guide for the direction in which traction should be made.

Professor Lazarewitch, of Cracow, followed. He maintained that the only curve essential to the forceps was the head curve, the pelvic and perineal curves being not only unnecessary, but mischievous. Forceps without pelvic or perineal curves answer best the mechanical requirements favorable to the action of the instrument, for the perineal curve is superfluous, inasmuch as the perineum can be readily distended as far as the coccyx without injury, while the pelvic curve increases the resistance to the passage of the head, endangers the soft parts, and renders the power of making traction in the axis of the pelvis difficult, if not impossible. Moreover, the direction in which traction should be made is decided by the muscular sense.

The universal opinion of the Section, however, appeared to be against Professor Lazarewitch's views, and in favor of the pelvic curve of the forceps. The chief objections raised against Professor Tarnier's instrument were its complexity and the danger with which it threatened the soft parts at the floor of the pelvis, and the continuous pressure it exercised upon the fetal head. Its complex character was seen and pointed out at its first introduction, and this was doubtless one reason why it had met with so little favor in England. The danger with which it threatened the soft parts of the pelvic floor was forcibly expressed by Fordyce Barker, while Matthews Duncan drew attention to the danger to the fœtus from persistent pressure on its head. The latter, with true wisdom, pointed out that a scientifically perfectly constructed instrument was not necessarily better than a scientifically imperfect instrument which had been gradually improved by generations of practitioners. Prof. Tarnier's instrument was on its trial; it had been constructed on theoretical principles, and time and experience by many practitioners in all parts of the world would alone decide whether the issue of M. Tarnier's labor and ingenuity was better suited for use in difficult midwifery than the product of long experience.

In a paper on

#### INTERMITTENT CONTRACTIONS OF THE PREGNANT UTERUS

as a means of diagnosis, by Dr. Braxton Hicks, the value of these changes in the organ in elucidating the diagnosis of tumors of the abdomen was pointed out, and illustrated by cases.

Professor Simpson, of Edinburgh, read a paper on a

#### COMMON NOMENCLATURE IN OBSTETRICS.

After some discussion it was resolved that a committee be formed, consisting of one representative of the several nationalities represented in the Congress, to draw up a scheme of common nomenclature, to be considered at the Obstetric Section of the next International Medical Congress; the representative of each country to consult with a committee of his fellow-countrymen.

Dr. Budin then read an interesting paper on a Peculiar Arrangement of the Membranes in Twin Pregnancy.

Dr. Battey next read a paper on

#### OÖPHORECTOMY,

in which he discussed, first of all, nomenclature; then the questions, "Is there a field for the operation, the indications for it, the method of performing it, and the proximate and ultimate results?" It appeared that there was a field for the operation; but, according to Dr. Battey's idea, a somewhat narrow one, for he had performed the operation sixteen times only during ten years; while, as shown by a table presented to the meeting, it had been done at Birmingham, by Mr. Tait, sixty-five times since May, 1879—that is, in a period of two years and three months. According to Dr. Battey, who presented a table of over two hundred cases with results, the mortality is eighteen per cent., and the cures in completed operations seventy-two per cent., in incomplete operations twenty-six per cent. Dr. Battey was followed by Dr. Savage, whose paper contained nothing of importance that has not been already published.

The discussion which followed the reading of these papers was the chief and most interesting of all those which took place in the Section. Mr. Knowsley Thornton called attention to the large proportion (eight per cent.) of cases in which the operation could not be completed, and concluded by stating that what was required before pronouncing the operation to be justifiable, was a clean mortality bill and a far more perfect record of the ultimate results than any yet given.

Dr. Martin, of Berlin, thought the operation should be done but very rarely. He deprecated haste in publishing cases, because a long time must elapse before the ultimate results could become known. For this reason he had not published his results. He had performed it fourteen times. Mr. Spencer Wells saw no cases demanding the operation. Dr. Goodell, of Philadelphia, had always followed the vaginal method in the operation, but would discard it in future, and adopt the abdominal. He suggested that it should be a part of the State Medicine of the future that the ovaries of insane women should be removed.

Dr. Matthews Duncan was a decided opponent of oöphorectomy; he regarded it as an operation which was in the crudest experimental stage. He had been for many years an observer of women's diseases, and

recently he had often been consulted as to oöphorectomy, and had sanctioned it in one case only, for he did not see the cases that required it. He regarded the sufferings of neurotic women as greatly exaggerated; he had never seen death follow them. He further pointed out, with reference to oöphorectomy for bleeding uterine fibromata, that a series of cases had been laid before the meeting—twenty-six cases, with five deaths. He knew of no similarly bad results under any other kind of treatment, and was sure that such disasters were unequalled in the history of the subject.

After the discussion on oöphorectomy, a group of five papers on subjects connected with displacements of the uterus were read. In a paper entitled "The Exciting Cause of Hysteria and Hystero-Epilepsy," Dr. Graily Hewitt traced such attacks to reflex irritation arising from compression of the uterine tissues from flexion of the uterus. Dr. Paul F. Mundé, of New York, discoursed on the "Curability of Uterine Displacements," and concluded that in cases of old-standing, permanent cure was extremely rare. Dr. Edis called attention to the many reflex disorders arising from uterine disease. Dr. Verrier, of Paris, described a somewhat formidable machine for redressing the displaced uterus, and Dr. Beverley Cole, of San Francisco, discussed the "Mechanical Treatment of Some of the Displacements and Diseases of the Uterus."

On the following morning the sitting opened with a paper by Professor Freund, of Strasburg, on

TOTAL EXTIRPATION OF THE UTERUS.

In the author's absence an abstract was read by one of the secretaries, Dr. John Williams. In this abstract Professor Freund unfortunately gave no statistics. Indeed, he confined himself to general statements and to a brief discussion of the two methods of removing the whole uterus—viz., the abdominal (Freund's) and the vaginal. He seemed to regard his method as a stage in the progress of the operation of total extirpation, and appeared to think that the vaginal method was to be preferred, especially in cases in which the uterus was small and the vagina capacious. He concluded that the operation might be undertaken as a not very dangerous one in the early stages of carcinoma and sarcoma, in which it gave a promise of radical cure.

A paper by Professor Corradi was read by Dr. Bantock, in which the author advocated total removal of the uterus by a combined vaginal and abdominal method. Dr. Martin, of Berlin, said that but few patients could be subjected to this operation. If the glands or broad ligaments were affected, the operation should not be done. He had removed the uterus six times after Freund's plan, and all the patients had died. He had removed it in seventeen cases by the vaginal method, and found no great difficulty in arresting the bleeding. The question of recurrence could only be settled after the lapse of sufficient time.

Professor Czerny, of Heidelberg, in consequence of the bad results he had met with by Freund's method, had adopted the vaginal operation, and had removed the uterus in this way seven times; four of the cases recovered, but recurrence had taken place in several. Professor Hennig, of Leipsic, advocated recourse to the operation, though the cases permanently cured be very few. Mr. Spencer Wells had never seen a case in which so serious an operation appeared justifiable. The cases were too far advanced, or were such as permitted the removing of the cancerous tissues by scraping or cutting, and the application of caustics, etc. Dr. Marion Sims also described his method, now well known, of treating cancer of the uterus.

Professor Slawjanski, of St. Petersburg, read an interesting paper on

A POINT IN THE DIAGNOSIS OF OVARIAN TUMORS,

in which he indicated a symptom which appeared to be diagnostic of the side on which the tumor grew. This sign was an impairment of sensibility in the inguinal triangle on the side of the affected ovary. He had examined five cases, and this was present in each case, and the accuracy of the diagnosis was verified by the subsequent operation.

Dr. Martin, of Berlin, read a paper, with illustrative cases, in which he advocated a new method of treating extra-uterine pregnancy, or rather a new method of treating the placenta and the sac in operating for extra-uterine pregnancy. He proposed to ligature, and had ligatured, the base of the placenta, and removed as much of the sac as possible, closing the remaining portion from the abdominal cavity, having previously drained it into the vagina. He stated that when the placenta was attached to the pelvic wall it could be ligatured as well as when attached to the uterus, and that in this way the placenta could be removed, and the danger of hemorrhage and of infection, in great part, if not entirely, obviated.

The next subject brought before the Section was the

SURGERY OF THE CERVIX AND VAGINA,

in two papers: one by Dr. Pallen, of New York, entitled "The Reparative Surgery of the Cervix and Vagina;" the other by Dr. J. H. Bennet, entitled "Lacerations of the Cervix Uteri: their Causes and Treatment." In the first paper a large number of questions were discussed, including the congenital deformities of the vagina and cervix, as well as the acquired conditions requiring plastic operation. Dr. Bennet found in inflammation the cause of lacerations of the cervix, and their treatment was the treatment of the inflammatory condition. The great subject of difference, however, between these two authors was the operation of Emmet for sewing the lacerated cervix, or trachelorrhaphy. Dr. Playfair discussed the question very fairly and fully, and explained how he had been prejudiced against the operation, and how he had come to change his views respecting it. He had done it in several cases, and found he had been enabled thus to cure some cases of long-standing illness. Dr. Goodell, Dr. Marcey, and others, paid a just tribute to Dr. Henry Bennet for the work he had done as a pioneer in the study of gynecology in England, but they could not agree with him in his estimate of Emmet's operation. Dr. Goodell thought it should be done in cases of lacerated cervix, even when there were no symptoms, with a view to prevent the development of epithelioma.

On Monday the work of the Section began with an address by Dr. Barnes, on the

TREATMENT OF PUERPERAL HEMORRHAGE.

Dr. Barnes entered somewhat fully into the conditions which predisposed to hemorrhage, and the physiological conditions which opposed it. This

part of his subject occupied so much of the time that he had but little to devote to the main subject of his paper. To guide in the selection of remedies, hemorrhage was divided into three degrees: 1st, the diastaltic function is maintained intact, but its action is disordered; 2d, the diastaltic force is markedly diminished; 3d, the diastaltic force is suspended. The usual means employed successfully in the first and second degrees were enumerated; they failed in the third. When muscular contraction failed, an equivalent might be found in styptics —iodine or iron. Iodine often failed; in iron we should put our trust. The author concluded that uterine injections of solutions of perchloride of iron were capable of averting bleeding when all other means had failed.

Dr. Moore Madden followed with a paper in which he discussed the prevention as well as the treatment of post-partum hemorrhage. He advocated a course of iron before labor, and the usual means, together with styptic injections, if necessary, after labor. Upon this question, especially the value of intra-uterine injection of solution of perchloride of iron, there was great difference of opinion. Some, as Matthews Duncan and Cole, rejected it in toto, trusting altogether to the retraction of the uterus, while others advocated its employment as a last resource when all other means had failed. The result of the discussion appeared to be that the cases which demand its use are extremely rare. The President dwelt upon the means of preventing hemorrhage. He gave a stimulant immediately the child was born. Chloroform predisposed to hemorrhage. He had in one case used injection of perchloride of iron with success.

An interesting and valuable paper upon an uncommon condition was read by Dr. Roper, viz., "Trismus and Tetany of the Uterus." He related seven cases—three of Smellie's and four occurring in his own practice. The treatment of the condition was extremely difficult, and no plan yet suggested was satisfactory.

After the exhibition of some instruments, a paper on "Delivery by Electricity" was read by Dr. Apostoli, of Paris.

Professor Spiegelberg had undertaken to open a discussion on

ANTISEPTICS IN MIDWIFERY.

Owing to illness, however, he was not able to be present, and his paper was read in abstract by one of the secretaries, Dr. Galabin. Having referred to the development of antiseptic views in surgery, he said that during labor the strictest cleanliness and antisepsis on the part of both mother and attendants should be observed; disinfection of the genital tract by frequent irrigation with antiseptics should be secured. Antisepsis after infection had taken place was not of much avail. It was only directly useful in processes of decomposition before the uterine parenchyma had become affected.

He was followed by Professor Winckel, of Dresden, who gave a report of the result of the introduction of antiseptic rules to the midwives in the kingdom of Saxony during the past twelve months.

After the reading of a paper by Dr. Halbertsma, of Utrecht, entitled "Puerperal Eclampsia is in most Cases the Consequence of Pressure on the Ureters," and one entitled a "Comparison between Embryotomy and the Cæsarean Section," by Dr. Eustache, of Lille, the last sitting of the Section closed.

## SECTION ON DISEASES OF CHILDREN.

THE TREATMENT OF SPINAL CURVATURE BY SAYRE'S METHOD.

The discussion of this important topic occupied the Section for two sittings. With the exception of Mr. Henry Baker and Mr. Reeves, there was a general concensus of opinion in support of Dr. Sayre. Mr. Henry Baker's paper was a *rechauffé* of the old views on the subject of extension, to the effect that its employment in the acute stage of spinal caries was dangerous, and in the late stage useless. Mr. Reeves referred to two cases of paraplegia and one of wryneck which had occurred after suspension, and held that the lengthening obtained was only transient. But it may be questioned whether either of these surgeons could bring forward any series of cases treated by old methods with results in the least comparable with those obtained by Dr. Sayre.

With respect to details of treatment, Dr. Oxley, of Liverpool, mentioned an ingenious device for renewing the singlet under the plaster corset. At the first application of the corset he used two singlets instead of one, and at intervals of a week or longer removed the inner one, by withdrawing it over the child's head, having previously tacked to its lower edge a clean singlet.

Dr. Oxley frankly admitted that in his early experiences he had sometimes over-extended. With some deference, he objected to Dr. Sayre's early demonstration of the difference in the shape of the curve before and after the extension, as giving rise to an erroneous view of the object to be sought. Dr. Oxley contended that the real object of the treatment was to take off the weight of the column from the diseased vertebræ, not to straighten the deformity; although, as a matter of fact, the spinal column was straightened as a whole, for the patient, instead of bending forward, and leaning his hands on his knees, or on some neighboring object, had his whole body above the diseased part supported and fixed.

Dr. Sayre, in a very vigorous speech, insisted with much emphasis on the danger of over-extension. He strongly condemned the suggestion of so distinguished a surgeon as Langenbeck, that the suspension should be preceded by anæsthesia. The limit of justifiable extension he had found again and again to be attained when the child showed signs of relief from pain after muscular spasm had been overcome. Dr. Sayre disavowed any desire to straighten the "boss" of the angular curvature, but he insisted that, even with the most careful maintenance of the horizontal position, inflammatory disease of a joint was sure to be accompanied by reflex contraction of muscles. This contraction was overcome by the suspension. Dr. Sayre gave some interesting cases of the successful application of his method to old people, the subjects of spinal caries.

The treatment of lateral curvature by Sayre's method was not fully entered upon, but Mr. Bernard Roth deprecated its use, except in extreme cases. Dr. Sayre regarded it merely as supplementary to the more important measures of massage and careful exercise of the weakened trunk and neck muscles. Amongst useful improvements for persons the subjects of lateral curvature, Dr. Sayre spoke of the homely one of making them walk with a book on the top of the head. Mr. Holmes in his summary of the use of Sayre's method in spinal caries, maintained that there were still lacunæ in our experience of the treatment in regard to the question as to

whether and how far symptoms of decided spinal irritation or inflammation had to be taken as contra-indicating it.

The discussion on the

PATHOLOGY AND TREATMENT OF GENU VALGUM,

which also occupied two sittings of the Section, brought out sufficient divergence of opinion to sustain the interest even of the medical part of the audience. As to the cause of the deformity, Mr. Lucas claimed that in almost every case it was the outcome of rickets, but this was by no means conceded either by the Vice-President or by Dr. Little, who showed that many other causes might give rise to it. Dr. Macewen held that in regard to the anatomy of the deformity in the typical cases, there was a twisting of the lower third of the femur and an actual intrinsic lengthening of the internal condyle, and that in about one-third of the cases there was a slight affection of the tibia likewise. As to the shape of the foot, Mr. Brodhurst held that it was flat, and that this indeed preceded the knock-knee; relaxed ligaments being, with him, the primary factor. Dr. Macewen strongly maintained that he always found the foot curved and arched on the inner side, and Dr. Little's explanation was that originally the foot was flat in these cases, but that when the patient with genu valgum tried to walk he turned the big toe inward as a compensating measure.

With regard to osteotomy, Dr. Ogston's operation, owing to the absence of its author, was but little referred to; but Dr. Macewen's super-condyloid method was well discussed, and some remarkable results set forth in support of it. In reference to age, Mr. Macewen declined to give any limit, but contended that the condition of the bones should be regarded as the true test; if there were ramollissement he would not perform the operation, whatever the age of the patient, believing that splints would effect what was required. As a matter of fact, eight years was the age of the youngest patient on whom he had operated, and he strongly deprecated the performance of osteotomy on young children. He had operated on 600 limbs, and of the three deaths in his practice not one had been due to the operation. Six only had suppurated. It was contended that the risk was not greater numerically than that of tenotomy. As to power of walking after the operation, Dr. Macewen referred to two recent cases, one a man aged eighteen, who, when admitted, had an interval of eighteen inches between his malleoli, and was unable to walk, except with great pain, but who six months after operation walked six miles daily with comfort, besides doing arduous work. The other patient who, when admitted, had an interval of fifteen inches between his malleoli, had, four months after operation, walked 100 miles in four days.

Dr. Little claimed that the cure for ordinary cases of genu valgum was to keep the knee extended, but he pointed out also that extreme flexion would succeed, and made the homely and valuable suggestion that amongst the poor a boy afflicted with this deformity should be apprenticed to a tailor, on account of the posture usual in that occupation. In the severe cases Dr. Little gave in his adhesion to Dr. Macewen's method of osteotomy. The *rationale* of the operation depended on the formation of a wedge of callus, succeeded by a mass of bone in the gap made by the chisel above the external condyle. The result of the formation of this new wedge of bone was that the external condyle was brought downward, and the interval which previously existed between it and the tibia was diminished.

Mr. Brodhurst advocated the mechanical treatment of the deformity, with the addition, in severe cases, of tenotomy of the external lateral ligament and of the biceps femoris. He made a vigorous onslaught on osteotomy as an operation unnecessary, ineffectual, and dangerous. Mr. Barker drew attention, however, to the fact that none of the dire results ascribed to osteotomy had followed upon Dr. Macewen's method, and quoted a case which had come under his own observation of a useless limb which had resulted from tenotomy of the external lateral ligament, performed for the relief of genu valgum.

The veteran French surgeon, M. Guérin, insisted on the classification of cases under two categories: (1) those where the deformity was due to muscular contraction, and (2) those where the relations of the joint were altered. In the 300 cases which had come under his observation he had never found osteotomy necessary. M. Fochier advocated the violent method known as *redressement brusque*, but this found no favor with any other speaker.

In summing up the discussion, Mr. Holmes obtained the hearty concurrence of the Section to his dictum, that if proper care and attention were given in early life, operative interference would never be required in these cases. He referred to the remarkable divergence of opinion as to treatment, in that M. Guérin, with an experience of half a century, should not have seen a single case where osteotomy seemed indicated; whilst Dr. Macewen, in a comparatively short period, had considered the operation desirable in no less than 600 limbs. Despite Dr. Macewen's hitherto excellent results, Mr. Holmes could not regard the artificial production of what was practically a compound fracture of the lower end of the femur as a procedure free from risk. He felt bound, however, to acknowledge the efficiency of the method, and that Dr. Macewen had made a distinct advance in surgery.

On the

SURGICAL TREATMENT OF EMPYEMA

little that was really novel was added to our knowledge.

Dr. Gerhardt insisted on the possibility of spontaneous cure of small empyemas by absorption, though he admitted that it was an extremly rare event. He drew attention also to the occasional cure by expectoration through the lung without the occurrence of pneumothorax.

The President and Dr. Ranke, of Munich, agreed in considering expectoration through the bronchi as a rarer event in children than in adults. Simple aspiration, on the testimony of several speakers, was claimed to be efficient in a certain number of cases. If this measure should be found ineffectual, there was a general consensus of opinion that incision and free drainage, with antiseptic precautions, should be adopted.

SCROFULOUS JOINT INFLAMMATIONS.

Prof. Hueter defined scrofulous joint inflammations as those in which the formation of masses of granulation tissue precedes suppuration, whilst in simple inflammation suppuration precedes the formation of granulation tissue.

He recommends the early injection by a Pravaz syringe of a three to five per cent. solution of carbolic acid into the incipient granulation tissue,

whether it be situated in the synovial membrane or in the medulla of bone. If this does not prove satisfactory, he recommends early excision. It was pointed out by Mr. Morgan that in the hands of English surgeons complete rest and fixation of the scrofulous joint had been followed by a considerable amount of success; that the treatment of diseased synovial membrane by carbolic acid had not borne the fruit which had been expected of it; and that excision of joints, with the exception of the elbow, had been repeatedly disappointing. Mr. Holmes also insisted that cases of joint disease, which everybody would agree to call scrofulous, had unquestionably recovered with rest, drainage, etc., and that the rule that if the injection of carbolic acid was not followed by improvement, excision should be adopted, was so absolute as to require much evidence to enforce its acceptance by English surgeons. Professor Hueter, in reply to the first observation, admitted that certain scrofulous inflammations of joints had subsided when at rest, but contended that they were cured by time, and not by rest. Dr. Sayre admitted that rest at the earliest time possible might effect a cure, but he objected to rest in bed in a hospital. He thought that only the inflamed joint should be at rest, that enough extension should be employed to take away pressure from the inflamed surface, and that as far as could be the investing tissues of capsule and the like should be exercised so as to keep up their nutrition.

The subject of

SURGICAL SCARLET FEVER

was well set forth in the paper with which Mr. Marsh introduced its discussion. The experience at the Children's Hospital, Great Ormond street, was quoted to show that whilst in the old hospital, where cases of scarlet fever were treated under the same roof as surgical cases, surgical scarlet fever occurred pretty often; in the new hospital, where the fever cases were treated under a separate roof, this complication was extremely rare. In regard to the entrance of the poison, Mr. Marsh did not favor the view that it was through the wound, on account of the latter remaining healthy. He was inclined rather to believe in the latency of the poison in the patient, and that in some sense it was precipitated by the operation or by the nervous depression associated therewith.

Dr. Goodhart stated that not only cases of operation wounds and of surgical disease, but even occasionally of phthisis, were liable to be attacked with this abrupt form of scarlet fever, and pointed out that the one thing in common was the presence of an inflammatory soil on which it might be assumed the germs of an acute specific poison could readily take root. That the surgical scarlet fever conferred protection from the ordinary form of the disease there seemed to be no doubt; but there was one link in the chain which it was desirable should be fitted in if the material was forthcoming—viz., were there any cases of ordinary scarlet fever capable of being imparted to others by a desquamating surgical scarlatina?

The discussion on

RÖTHELN

elicited a fairly concurrent account of the ordinary type of this mild but definite exanthem. It was, however, clearly demonstrated from Dr. Cheadle's important communication that occasionally this disease can assume a severe or malignant form. Dr. Cheadle related examples in which there was recurrent vomiting, severe earache, and laryngeal obstruction, so intense in some cases as to require tracheotomy. That these severe cases were true rötheln, and not measles, as at first believed, was proved by their breeding undoubted rötheln of the mild uncomplicated type in persons exposed to their infection.

On the

RELATIONS OF CHOREA AND RHEUMATISM

there was considerable disparity in the numerical results obtained respectively by Dr. Stephen Mackenzie and Dr. Octavius Sturges. In analyzing one hundred and seventy-two cases admitted into the London Hospital during six years, Dr. Mackenzie had found that there was some cardiac abnormality in more than half the cases; that in more than eighty per cent. the heart-lesion persisted; and that there had been pre-existent rheumatism in nearly fifty per cent. Dr. Sturges found that of one hundred and twenty-one cases under his care at the Highgate branch of the Children's Hospital, ninety-seven were free from any history of rheumatic manifestation. He strongly maintained the functional nature of chorea, and its tendency to spontaneous recovery independently of any kind of medicinal treatment.

Dr. Byers, of Belfast, pointed out that there was considerable evidence to show that rheumatic endocarditis was the connecting link (the chorea being due to emboli), but he held that the embolic theory would not explain all the cases, and quoted examples where there was no rheumatic history and no murmur. In order to include both rheumatic and non-rheumatic cases, it would seem necessary to refer the primary fault to some disturbance of the nervous system, and this was not inconsistent with the view now held by many, that rheumatism is itself a disease of the nervous system.

Dr. Ranke, of Munich, thought the geographical distribution of disease of great importance. In regard to chorea he thought its relative frequency must vary considerably in different districts. He found from his case-book that since 1867, out of forty thousand seven hundred and twenty-three children treated by him at the University Dispensary at Munich, only nineteen cases of chorea had been treated. Of these three had presented a systolic murmur, in all the others the heart-sounds had been found normal. There was only one child in whom a previous attack of acute rheumatism had occurred. Of the nineteen cases the chorea in two had followed upon fright; in all the rest no immediate cause could be discovered.

Drs. Barlow and Warner read a joint paper on the occurrence of

SUBCUTANEOUS NODULES IN CHILDREN

the subjects of chorea and rheumatism. The paper was an analysis of twenty-seven cases which had come under their observation. The nodules described varied in size from that of a mustard seed to that of a bitter almond. They were strictly subcutaneous, being attached to tendons or the deep fascia, especially near joints. In minute structure they consisted of connective-tissue cells, young fibrous tissue and vessels, and appeared either in one or several crops. They usually subsided within two months, but might reappear. They were painless. Their evolution was unattended by pyrexia. The importance of these nodules did not depend on

anything intrinsic, but on their clinical associations. In all the cases there was heart disease, often grave and progressive in character. There was history of rheumatism in about two-thirds of the cases, and of erythema marginatum in more than one-fourth of them. Twelve out of twenty-seven cases had chorea.

It was submitted that the occurrence of these nodules might be taken as indicative of rheumatism in children; that when found associated with heart disease and chorea, although no history of rheumatic fever could be obtained, nevertheless their presence gave a presumption that the chorea was rheumatic; that in nature they were probably homologous with the inflammatory exudation which formed the basis of a vegetation on a cardiac valve.

## SECTION ON OPHTHALMOLOGY.

After the reading of the President's address, an abstract of which has been published in a previous issue, on the motion of Mr. Critchett, a committee was appointed by the section to deliberate concerning the tests of vision and color sense most applicable to persons employed in working or observing signals by land and sea, where the lives of others are involved, and to report thereon to the council. This committee comprises many of the most eminent ophthalmic surgeons from the various countries represented at the Congress.

The discussion on the

ANTISEPTIC METHOD IN OCULAR SURGERY

was opened by Professor Horner, of Zürich. Taking the statistics given by Noyes and Geissler of the results of cataract extraction, as showing a loss of 10.1 per cent. by the flap and 4.8 per cent. by the linear operation, Professor Horner alleged that by strict antiseptics, such as the prophylactic disinfection of the patient, operator, and instruments, etc., and by antiseptic dressings after the operation, we may hope to reduce the losses to 1.5 per cent.

Professor Reymond followed in the same direction as Professor Horner, and insisted that, in order to carry out Listerism in cataract-extraction, the dressing should extend far beyond the orbital region, and should be very accurately applied. In three hundred and fifty extractions since January 1, 1880, Professor Reymond had had primary sloughing of the cornea in seven patients, of whom four had taken off the bandages themselves before the third day.

In connection with the same subject, Professor Th. Leber, of Göttingen, read a paper on the

ACTION OF FOREIGN BODIES INTRODUCED INTO THE EYE,

in which he maintained that the purulent inflammation which supervened on the introduction of metallic fragments into the eye was always due to the action of germs which had entered through the wound. Purulent inflammation might, however, be set up independently of the action of germs by the introduction into the interior of the eye of certain chemical substances, such as arsenic, binoxide of mercury, etc. The extracts of septic liquids in which the germs had been killed by boiling set up transient inflammation when injected into the anterior chamber or into the corneal tissue.

Various conflicting opinions were expressed in the discussion following these three papers. Dr. Knapp, of New York, maintained that the inflammation that followed cataract-extraction was due more to injury of the cornea than to infection. On the same day papers were read by Dr. Landolt, of Paris, on "Motor Affections of the Eyes," and by Dr. Abadie, of Paris, on "Partial Tenotomy of the External Recti in the Treatment of Insufficiency of the Internal Recti." Dr. Javal, of Paris, showed his beautiful and ingenious apparatus for the subjective and objective determination of astigmatism.

On the third day, Professor Snellen inaugurated an important discussion on

SYMPATHETIC OPHTHALMITIS,

by an ingenious paper on the nature of this disease, and the mode of its transmission. Alleging the insufficiency of the explanation of a reflex action of the ciliary nerves, he proposed the hypothesis that sympathetic ophthalmitis should be regarded as a metastatic specific inflammation, in which special parasitical inflammatory elements were conveyed over to the choroid of the sympathizing eye through the dilated lymph-paths. Dr. Brailey followed with a paper on the pathology of the disease, in which he maintained that the uveitis which is met with in this disease presents certain definite pathological characters by which it could be distinguished histologically from all other forms of inflammation. He also agreed that the disease was not transmitted from one eye to the other by the passage of structural change along either optic or ciliary nerves. Dr. Poncet, of Cluny, then related a case in which, in an eye enucleated after enervation, for sympathetic mischief, examination showed changes of unusual intensity, due to the optico-ciliary neurotomy. He ascribed the permanence of the sympathetic pains to an interstitial sclerosis with irritative compression of the fibres of the peripheral ends of the ciliary nerves. A lively discussion followed, in which Drs. Mooren, Grünhagen, Samelsohn, Leber, Bouchut, Panas, and others took part.

Dr. Liebrecht, of Ghent, then recorded some practical observations on the examination of railway servants and seamen as to vision and color-blindness. Dr. Ole Bull, of Christiania, related a new method of examining and numerically expressing the color perception, and Mr. Eales, of Birmingham, read a short paper on Primary Retinal Hemorrhage in Young Men.

The fourth day was chiefly occupied with a discussion on

OPTIC NEURITIS

in connection with intracranial and spinal disease. Professor Th. Leber stated that optic neuritis in cerebral disease was a true inflammation, and was very different from the hyperæmia caused by venous stasis and the lesions which depended on it. This inflammation, he said, was not caused by stasis in the retinal veins from compression of the cavernous sinus, due to diminished intracranial space, nor was it the result of irritation of vasomotor nerves caused by the cerebral affection. It was the optic nerve which was the path of communication between the affection of the brain and that of the eye. An essential part in this transmission was taken by the effusion of a serous fluid into the sheath of the nerve extruded from the cranium by the increased intracranial pressure. This fluid did not act by simple mechanical pressure, since its quantity was sometimes small; probably it possessed phlogogenic properties. Intracranial tumors acted as a sort of foreign bodies, provoking inflammatory congestions and hypersecretion of fluid (internal hydrocephalus). The same effusions were found in meningitis when

it was followed by papillitis. The origin of papillo-retinitis in cerebral diseases might be explained by assuming that the intracranial inflammation produced serous effusion, which passed into the optic sheath, and exerted an irritating action on the papilla and neighboring parts of the eye.

In a paper on the

RELATION BETWEEN OPHTHALMOSCOPIC CONDITIONS AND INTRACRANIAL DISEASE,

Dr. Bouchet, of Paris, held that all the important diseases of the brain and cord, as well as the serious diathetic diseases, might be recognized by ophthalmoscopic examination. Thus, he argued, congestion and swelling of the optic nerve indicated congestion of the brain, meningitis, compression of the brain, or commencing spinal disease; œdema of disk and neighboring retina showed œdema of meninges and obstruction to circulation in the sinuses and meningeal veins, in tubercular meningitis, in acute and chronic hydrocephalus, in cerebral hemorrhage, in certain cerebral tumors accompanied by encephalitis, etc. Retinal varices and thrombosis indicated thrombosis of the sinuses and meningeal veins. Miliary aneurisms of the retinal arteries showed miliary aneurisms of the brain. In fevers and diseases of the nervous system, retinal hemorrhages indicated either compression of the brain by a copious effusion, the hemorrhagic diathesis, cardiac obstruction to the cerebral circulation, or changes in the cerebral and retinal vessels caused by chronic albuminuria, glycosuria, syphilis, and leucæmia. Miliary tubercles of the retina and choroid showed tuberculosis of the brain or meninges. Lastly, in nervous diseases, atrophy of the disk or sclerosis of the optic nerve always indicated a disseminated sclerosis of the brain or of the anterior columns of the cord.

After these followed a paper by Dr. Dianoux, of Naples, on the

TREATMENT OF DETACHMENT OF THE RETINA BY INJECTIONS OF PILOCARPIN,

in which it was stated that of sixteen cases treated by methodical injection of nitrate of pilocarpin six were cured, eight improved, and two were unsuccessful. The plan of using was explained and the contra-indications set forth. The dose recommended was strong at first, then moderate (salivation of at least two hours' duration); a series of fifteen consecutive injections should be given and then a rest for a week, and the treatment should be steadily kept up for three months.

REPORT OF THE COMMITTEE ON COLOR-BLINDNESS.

The business of the fifth day was begun by the Committee on Color-Blindness presenting its report. As regards persons working on land, the committee recommended a continuance of the rules adopted at the last International Congress at Amsterdam. For use at sea, the committee recommended that in all ocean-going ships the steersman and look-out man should have normal acuteness of vision and color sense, and that those in coasting vessels should have at least two-thirds of the normal standard. The officers and pilots, and all concerned in navigation, should have normal acuteness, there being no more than one dioptre of manifest hypermetropia up to the age of eighteen, and not more than one dioptre and a half above eighteen years. The committee further urged that all persons should be carefully re-examined at the age of forty-five by competent experts.

After this followed a discussion on

GLAUCOMA,

begun by Dr. Adolf Weber, of Darmstadt, with a paper on "The Pathological Changes Preceding and Causing Glaucoma." He pointed out that, amongst the changes preceding glaucoma, we very commonly observed disturbances of the general circulation, which diminished the difference between the arterial and venous pressure, to the disadvantage of the former. General nervous conditions were only so far of importance in glaucoma as they led to these circulatory disturbances. Morbid changes in the tissues, such as were found in old age, aided in causing glaucoma only as they affected the walls of the blood-vessels. After explaining the mechanism of the interchange of fluids in the eye, he concluded by stating that the only invariable antecedent, and, in that sense, cause of glaucoma, was a progressive contraction of the outlets of the intra-ocular fluids; the other antecedents, neither alone nor combined, could produce it. The clinical varieties of glaucoma, he said, depended on the seat, intensity, and extent of the contraction or obstruction in the efferent channels, on the primary or secondary character of this morbid process, on its inflammatory or non-inflammatory nature, the reaction on the circulation in the vessels, and its slow, acute, or destructive character.

Dr. Laquer, of Strasbourg, followed with a paper on "The Changes in Refraction which Occur in Glaucoma," and then Mr. Priestley Smith, of Birmingham, reiterated his views of the pathology of glaucoma. Dr. Angelucci, of Rome, then described the nature of Descemet's membrane and the development of the canals of Schlemm and Fontana, in relation to the etiology of glaucoma. The cause of glaucoma was, he thought, not to be found in the closure of Fontana's canal, which was a secondary change, but in sclerosis of all the membranes of the eye, and chiefly of the walls of the blood-vessels.

Dr. Knapp, of New York, gave an account of his operation of extraction of cataract by peripheral division of the capsule. After this operation, he had obtained, he said, the following average results: 90 per cent. of the cases had acuteness of vision varying from $\frac{10}{10}$ to $\frac{10}{200}$, 5 per cent. from $\frac{5}{100}$ to $\frac{1}{200}$, and 5 per cent. from nothing to perception of light.

The greater portion of the sixth and concluding day was devoted to a consideration of the treatment of glaucoma. Dr. de Wecker, of Paris, discussing the relative merits of sclerotomy and iridectomy in glaucoma, said that sclerotomy will be resorted to in those cases in which iridectomy is known to be dangerous—viz.: in glaucoma hemorrhagicum, or in glaucoma congenitale, or glaucoma infantile, otherwise known as buphthalmic hydrophthalmia; also where iridectomy is unreliable—that is to say, according to von Graefe's own admission, in simple chronic glaucoma, with the absence of any inflammatory symptoms. Also in those cases where the visual field has contracted nearly to the point of fixation, it is unsafe to remove any iris. Prolonged experience had, he said, satisfied him that the scleral incision alone is the best, most complete, and safest in simple chronic glaucoma. Experience had shown that a glaucoma simplex, which has resisted sclerotomy, is not to be cured by an iridectomy. The most striking results are got from iridectomy in acute glaucoma; and it might be said that the more acute the glaucoma, the more successful the operation is likely to be.

Dr. De Wecker concluded that sclerotomy was indicated: 1. In all forms of hemorrhagic glaucoma, and in those suspected of belonging to this category; 2. In all cases of glaucoma congenitale (buphthalmia); 3. In all cases of chronic simple glaucoma; 4. Whenever, after an iridectomy, the vision has deteriorated, or when the good result of this operation begins, after a period, to diminish; 5. In combating the prodromata of glaucoma; 6. In all cases of glaucoma absolutum, with complete atrophy of iris, and attacks of pain. Dr. Bader went somewhat farther, and laid down: 1. That the kinds of glaucoma treated by iridectomy can be treated, and more successfully, by sclerotomy; 2. That to secure success it is desirable to maintain a staphyloma of the conjunctiva, with or without prolapse of the iris. He showed several striking cases in support of these two propositions. Dr. Abadie, of Paris, on the other hand, maintained that sclerotomy was most suitable in cases of increased tension with deep anterior chamber. An interesting and animated discussion ensued, in which Mr. Power, Dr. Panas, Dr. Argyll-Robertson, Dr. Knapp, Dr. Samelsohn, and M. Galezowski took part. Dr. Hermann Pagenstecher, of Wiesbaden, subsequently described a new operation for the cure of ptosis, in which he established a firm cicatrix between the drooping lid and the adjacent frontalis muscle.

Dr. G. T. Stevens, of New York, then read a paper on "Oculo-neural Reflex Irritation," the conclusions of which were: 1. That among the centripetal influences which generate nervous affections, the irritation arising from a perplexity or exhaustion of nerves in performing the functions of adjustment of the eyes must be regarded as of great importance; 2. That when a family tendency to neurotic affections is found, the inherited tendency is often transmitted in the form of the eyes or the condition of their accessories; 3. That inveterate cases of functional nervous diseases not amenable to other forms of treatment will often yield readily to the simple process of relieving the eyes from muscular or refractive disabilities.

## SECTION ON DISEASES OF THE EAR.

The first subject for discussion was the value of operations in which the tympanic membrane is incised. Dr. Paquet read a paper on

### A MODIFICATION OF MYRINGODECTOMY FOR SCLEROSIS OF THE EAR.]

The author claimed for his operation the double advantage of a permanent opening and division of the tensor tympani muscle. In one case he was able to keep the perforation patent for two years. Dr. Paquet, however, did not inform the members what advantage beyond a permanent opening he hoped to obtain by the operation, nor did he explain how his operation effected what all other varieties of myringodectomy have failed to do—namely, a permanency of the opening. Dr. Guye, opening the discussion, divided the cases in which myringodectomy was advisable into four classes: first, in acute inflammation, with pus or muco-pus in the tympanic cavity; second, subacute or chronic inflammation, with a large accumulation of tenacious mucus; third, in chronic proliferous catarrh, attended by nervous symptoms, such as vertigo or tinnitus, etc.; fourth, in certain anomalous cases, as, for example, cases in which, owing to the patency of the Eustachian tube, the fluid, as secreted, escaped into the pharynx, and thus did not accumulate in sufficient quantity to exert enough pressure on the membrana tympani to cause its rupture, and yet enough to cause considerable pain. To these Dr. Loewenberg proposed to add cases of inflammation of the mastoid cells. In such myringodectomy cut short the inflammation and relieved the distressing pain. Mr. Dalby pointed out that most surgeons were agreed as to the advantages of the operation in the first two classes of cases; but the important question was, by what signs or symptoms could we, in any case of dry proliferous catarrh, tell that such a case would or would not be relieved by the myringodectomy? It must be admitted that the experience of most English surgeons was, so far, against the operation in the third group of cases; and, as Dr. Pritchard pertinently asked, "Are we justified in incurring the risk of making a patient worse for the very uncertain chance of making him better?"

Dr. Cassells read a paper on the

### ETIOLOGY OF AURAL EXOSTOSES.

The author drew a distinction between aural exostosis and hyperostosis. The former, he maintained, was a new growth, the latter a hyperplasm. They differed in origin, shape, structure, and number. In the discussion which ensued the speakers did not draw the distinction between exostosis and hyperostosis, but discussed them both under the general term "exostosis." Dr. Guye believed that multiple exostoses never completely occluded the meatus; as soon as the tumors attained sufficient size to come in contact with one another, they ceased to grow, thus leaving a small central passage. Dr. Loewenberg mentioned a curious case, in which the exostoses, without touching, were connected with one another by thin bridges of bone. The treatment of hyperostosis by the dentist's drill was generally agreed to be the best. Dr. Pritchard, however, related a curious case, in which, after drilling into the tumor, it was subsequently treated with a weak solution of nitric acid. At the end of some two months or more the bone was found to be so much softened that he was able to break off the tumor. Dr. Knapp, of New York, gave the result of his very interesting examination of two hundred and fifty skulls of the mound-builders of America. He found exostoses in forty-four; the exostoses were all rugged and on the posterior wall. They were supposed to be produced by the mechanical irritation of foreign bodies long kept in the external auditory meatus. Dr. Gellé and Dr. Loewenberg arrived at opposite conclusions as to the frequency of aural exostoses in France—the former considering them rare, the latter common.

Dr. Gellé read an instructive paper on "Nerve-Lesion Deafness," and Dr. Stevenson one on "Certain Conditions of the Eyes as a Cause of Loss of Hearing by Reflex Irritation." Dr. Knapp recorded a case of loss of hearing from mumps, and thought that other diseases most likely to affect the portio mollis nerve were cerebro-spinal meningitis and syphilis. Dr. Barr more accurately classified the causes of nervous deafness into three groups: 1. Affections of the tympanic cavity, involving secondarily the acoustic nerve; 2. Syphilis; 3. Hyperæmic disturbances. Dr. Knapp related some interesting experiments on the loss of vision and hearing following the use of large doses of quinine. The loss was temporary in both. In the case of vision the return of sensibility passed from the centre to the periphery, but did not reach completely to the periphery. The arteries of the retina disappeared.

The veins were scarcely traceable, and the disk looked atrophic. The field of vision was narrowed on the inner side, not so much on the temporal. Color perceptions were also diminished; objective symptoms in the ear were negative. He believed the poison acted centrally. Mr. Dalby probably expressed the opinion held by very many present, when he stated that although the effects of quinine on the ear, even in large doses, were temporary, the continued use of large doses did produce permanent impairment of hearing. Dr. Jones, of Chicago, however, stated that he had never seen a case of the ill effects of the continued use of quinine, and believed that sufficient allowance was not made for the effect of the malarial poisoning. If quinine acted injuriously on the hearing, it would do so much as the long-continued use of any stimulant (such as tea, coffee, tobacco, etc.) would, by exhausting the nervous system.

On Monday, Dr. Fournié read a paper on the

FUNCTIONS OF THE EUSTACHIAN TUBE.

He believed he had proved by experiment that one of the essential functions of the tube was to prevent unpleasant resonance of external and internal noises. This function assumed a permanent opening of the tubes, and he believed that the muscles which were usually considered dilators were in reality obturators of the tube. Dr. Rumbull did not agree with the views of Dr. Fournié, but believed that the air in the tympanic cavity was always in a state of slight rarefaction. This kept the membrana tympani tense and slightly concave. He believed that the tube was always slightly open, and not during deglutition only. He cited the following experiments in proof: 1. If the limit of hearing be taken with a watch, and the experimenter swallows with the nostrils closed, the sound of the watch is lost. If now the act of deglutition be performed with the nostrils open, hearing is improved, but is not so good as at first for some little time, showing that some air enters gradually after the act of swallowing. 2. If, after taking the limit of hearing, the tympanum be inflated by Valsalva's method, the hearing is diminished; on swallowing the hearing will improve, but will not reach the previous limit for some time.

Dr. Knapp, of New York, followed with a paper on "The Cotton-Wool Pellet as an Artificial Drumhead." An abstract of his views has been previously published in our columns.

Dr. Gardner-Brown next demonstrated an ingenious method for estimating the hearing power in health and disease. The author has conceived the idea that the point in the lessening amplitude of the vibrations corresponding with the moment of their loss to the sense of touch in the thumb and finger of the examiner, forms an excellent and convenient standard of reference for the auditory perceptivity of the patient.

The space at our command prevents us from more than mentioning the remaining papers, viz.: "Objective Noises in the Ear," by Dr. Fitzgerald; "The Accommodation of the Ear," by Dr. Gellé; "Paretic Deafness," by Dr. Woakes; "The Action of Syphilis on the Ear," by Dr. Pierce; "Caseous Accumulations within the Middle Ear, regarded as a Probable Cause of Miliary Tubercle," by Dr. Barr; "Some Difficulties presented in the Diagnosis, Prognosis, and Treatment of a Certain Form of Middle-Ear Deafness," by Dr. MacBride; "On the Prevention of Dumbness in those Cases where it follows Loss of Hearing," by Mr. Arthur Kinsey; "A Fluid Artificial Membrana Tympani," by Dr. Michelle. Among these, we would call special attention to the valuable paper of Dr. Woakes, which was unfortunately taken rather late in the meeting, but which will well repay perusal; and also to the one by Mr. Arthur Kinsey.

The meetings terminated with a vote of thanks to the President, Mr. Dalby, and the two Secretaries, Drs. Purvies and Pritchard, for the admirable manner in which the meetings were managed.

---

## SECTION ON DISEASES OF THE TEETH.

The Section opened with an address from its President, Mr. Saunders, and an interesting paper by Professor Owen, both of which we omit for want of space.

The first subject propounded for discussion was that of

REPLANTATION AND TRANSPLANTATION OF THE TEETH.

Dr. Magitot described his method of replantation, and gave a record of ninety-two per cent. of successful cases. The general conclusion derived from the discussion which followed seemed to be that this operation should be adopted only when a tooth was otherwise in a hopeless condition, that the ends of the roots should be excised and smoothed, but that invariably successful results had been attained when sound teeth had been accidentally extracted and at once returned to their sockets.

An interesting summary of the experiences of Messrs. Clover, Braine, Bailey, and Coleman, read by the last-named, in the administration of anæsthetics at the Dental Hospital, Leicester square, since 1868, shows a total of more than 20,000 cases. Chloroform, gas, ether, nitrous oxide, and ethidene were given without a single fatality resulting from their use.

An important subject,

DENTAL SURGERY IN THE ARMY AND NAVY,

was brought forward, and it was strongly urged that a course of lectures on, with practical training in, the preservation of the teeth, should be included in the special subjects at military and naval medical schools, so that the health of our soldiers and sailors should not be endangered by the wholesale extraction of teeth.

A question of much interest to dental surgeons was debated during the most of one morning—the causes and treatment of premature wasting of the alveoli and loosening of the teeth. Various theories as to the causes were advanced. The edges of the alveolar sockets were implicated in the disease, and there was no doubt that the only efficient treatment was to scrape away, with suitable instruments, not only all tartar on the teeth, but also diseased portions of the socket until healthy bone was reached, and, in addition, to paint these portions with phenylic alcohol.

Mr. John Tomes, F.R.S., read an essay on

DENTAL EDUCATION,

which dealt most completely with the question, and was cordially accepted by the English, American, and foreign representatives as the ideal system. Mr. Tomes pointed out that the preliminary examination in arts was the same for the license in dental surgery as for the membership of the College of Surgeons of England, and that whilst most of the subjects in the two curricula were also the same,

where they diverged the difference was one of kind and not of degree, both costing the same in time, labor, and money.

A subject of general interest was discussed in a joint session of the Sections for Diseases of Children and for Diseases of the Teeth, when Dr. Magitot read a paper on "Honeycombed Teeth as an Evidence of Infantine Convulsions." This produced a good discussion, and elicited from Mr. Jonathan Hutchinson an expression of his now well-known views about the teeth. He stated that the true syphilitic teeth could not be mistaken, the characters being most marked in the upper permanent centrals. The normal tooth when first cut had at its incisive edge the appearance of three denticles (described by Mr. Moon), but in the syphilitic tooth the middle denticle was absent, and this caused the tooth to appear pinched and conical. After twenty years' experience he stated that though only, perhaps, present in one case in five, these teeth were certain evidence of hereditary syphilis. Honeycombed teeth were simply defective in structure, irrespective of shape, and Mr. Hutchinson believed this to be due to mercury given in infancy, be it for syphilis or other disorder.

In the discussion on the influence of septic agencies in causing caries of the teeth, Mr. A. Underwood and Mr. W. T. Mills read notes on their experiments, and showed some specimens of carious dentine and cementum, in which the presence of bacteria and micrococci was distinctly and beautifully demonstrated under $\frac{1}{25}$ objectives. They found that they could produce apparent caries in teeth placed in meat solutions and kept warm, with abundance of bacteria and micrococci in the tubules and lacunæ, as well as in the fluid, which became acid, but that when other flasks and teeth were rendered aseptic by the usual methods, no caries was produced and no germs detected.

Other papers by Dr. Norman Kingsley and by Mr. Mummery, on the causes of the increased degeneracy of teeth at the present time, were read. The former stated that the increase of nervous diseases correlated to deterioration of the teeth, each influencing, and in a measure, causing the other; whilst the latter imputed to the modern system of over-stimulating the nerve-power by too early education a defective power of assimilation and tissue formation, especially of the teeth.

The treatment of irregularities of the teeth and jaws was dealt with by several writers, and Mr. Coffin's system of expansion was justly appreciated. Mr. Coleman explained the vexed question of erosion of the teeth as being entirely due to friction over degenerated portions of tooth-substance.

## SECTION ON PHYSIOLOGY.

After the President's address, a discussion was opened by Professor Goltz, of Strasburg, on the

### LOCALIZATION OF THE FUNCTIONS OF THE CEREBRAL CONVOLUTIONS.

After a short historical review of the subject, the speaker referred to the experiments which he had made to ascertain whether the assertion of Flourens was true, that large parts of the cerebral tissue could be removed without causing apparent loss of function.

The method which Professor Goltz first employed, consisted, as he reminded the Section, of exposing the surface of the brain, and then washing away large portions of its substance by subjecting it to the action of a powerful stream of water. It was found that the statement of Flourens could not be accepted without reservation. After the destruction in the way indicated of large parts of one side of the brain, there results, for instance, hemiplegia, which is, however, not permanent, but transient, with cross-blindness. After destruction of large parts of both hemispheres by the same method, Goltz found that there was produced a permanent affection of the senses, which were observed to be dulled to an extraordinary degree, without being, however, lost. During the last two years, Professor Goltz, abandoning his earlier "washing away" method, has destroyed limited parts of the cerebral surface by means of circular drills with cutting and tearing edges, which, when rapidly rotated, destroy the part of the brain in which they are placed. By removing large parts of the skull-cap, and using such instruments, Professor Goltz has produced either very localized or very extensive lesions, of which he has studied the results—the dog being invariably the animal chosen for experiment. The results differed according as the anterior or posterior halves of the upper surface of the convolutions were destroyed. Without referring in detail to the various experiments of Professor Goltz, we have to draw special attention to his remarkable assertion that in the dog, after removal by his procedure of the greater part of the gray matter of the hemispheres, of the motor areas, and of the sensory areas, the animal may recover and live for a long period of time, without exhibiting any definite paralysis whatever. Such a dog, according to Professor Goltz, can see, taste, smell, feel—yet all these senses are dulled. It can move—yet its movements are clumsy. It has none of the paralysis of movement, and none of the losses of special senses, which the doctrines of Ferrier and of Munk would lead us to predict. But is the creature entirely normal? No, as Professor Goltz proceeded to state. Though the animal is not stone-blind, and can see, hear, and feel in a certain manner, yet perception is greatly interfered with, and the intellectual functions are weakened; the dog is in the condition of one demented, and many of its instincts are found to be perverted.

Professor Ferrier succeeded Professor Goltz, and stated *in limine* that he was prepared to accept the facts of so eminent an observer, though he rejected his conclusions. Until it is proved that the phenomena observed by Professor Goltz are dependent upon the gray matter of the hemispheres, it may be assumed that they are phenomena which require, in the case of the dog, merely the integrity of the great basal ganglion. He called the attention of the Section to the fact that Professor Goltz's experiments had been performed entirely on dogs, and he deprecated the drawing of general conclusions from experiments performed upon one animal species only. Without disputing the facts described by Professor Goltz, he would bring before the Section other facts, observed by himself in the case of the monkey, and which entirely corroborated his own views in reference to cerebral localization. Professor Ferrier said that by the galvano-cautery and the antiseptic method he had been enabled to establish definite and permanent cortical lesions. By this method he had corroborated his former experiments, and had produced permanent paralysis as well as loss of special senses.

The interest in the discussion culminated when the members were taken to see Ferrier's monkeys and

Goltz's dog. The one monkey had his left motor area destroyed, and was hemiplegic; the other had had the auditory area cauterized, and was completely deaf.

The dog, on the other hand, had, according to Goltz, been deprived of the larger part of both hemispheres, including the motor areas. Yet he only showed some clumsiness of movement and dulness.

The animals were subsequently killed, when it was found that the lesions in the monkeys were just as had been claimed, while the dog had not lost as much brain tissue as had been asserted.

The second debate was opened by M. François Franck, on the

MECHANISM BY WHICH THE HEART-BEAT IS REGULATED AND MAINTAINED.

After referring to the first observations on the rhythmical contractions of voluntary muscle made by Brown-Séquard in 1849 and 1853, and by Schiff in 1863, M. François Franck drew special attention to the experiments made in Ludwig's laboratory by Merunowicz and other observers, and which show that the isolated apex of the frog's heart, when subjected to the action of defibrinated blood or serum, beats rhythmically, and to the more recent observations on the same subject by Bernstein, Luchsinger, and Gaskell.

Dr. Gaskell followed the first speaker. One of his most important conclusions was, that the inhibitory action of the vagus is to be explained by its direct action upon the muscular tissue of the heart, and not upon an intermediate nervous apparatus—the nerve probably possessing the power of regulating the transformations of matter in the muscular substance, so as to affect the readiness with which these fibres are influenced by impulses reaching them from the motor centres. According to this view, the vagus would be the great trophic nerve of the heart. Space will not permit of our referring to the observations of Dr. Brown-Séquard, Professor Kronecker, or Dr. Carpenter, who called the attention of the Section to the interest attaching to the study of the movements of the heart of ascidians.

The next debate, upon

ANIMAL HEAT,

was opened by Dr. H. C. Wood, who reviewed his elaborate studies upon this subject.

Dr. Burdon-Sanderson, following him, referred to the errors which had hitherto been inherent to observations with the calorimeter, and to the remarkable improvements lately introduced into calorimetrical methods by M. D'Arsonville, who places his calorimeter in chambers of constant temperature, and who employs the graphic method to record continuously the changes in the volume of water of the calorimeter, which correspond to changes in its temperature.

Professor Kronecker recalled the observations made by him and by a pupil, with the aid of his maximum registering thermometers, and which proved how great an influence on the production of animal heat was exerted by the secreting apparatus situated in the walls of the alimentary canal.

The meeting of the Section on Monday was opened by a discussion on the

MICROSCOPICAL APPEARANCES OF STRIPED MUSCLE DURING REST AND CONTRACTION.

Professor Rutherford, of Edinburgh, who opened the discussion, gave a résumé of the views hitherto held on this difficult question, and then detailed the results of his own observations on the muscle of the crab, prepared by a new method. He entirely supports the theory expressed by Kölliker, that the sarcous substance essentially consists of fibrils united by a small amount of interstitial material. He finds eosine and aniline blue of much service in differentiating the several parts of the fibrils, the sarcous elements and the so-called Krause's membrane being readily stained by them. The sarcous elements are shaped like minute dumb-bells, with a slight swelling in the middle of the shaft, in the position of Hensen's stripe. The thin, dim line in the clear stripe, first described by Dobie, of Chester, and commonly named Krause's membrane, is due to a row of globules, as Busk and Huxley first indicated. The clear, as well as the dim, segments of the fibrils shorten during contraction. The refractile material of the sarcous elements moves toward their ends, leaving the shafts clear. The shafts of the shortened sarcous elements then become the clear stripe, while the original clear stripe is rendered dim by the transference of the refractile material of the sarcous elements to the immediate neighborhood of Dobie's line. This explains the "reversal of the stripes" in contracted muscle. The different stages of the transition may be clearly traced after staining with eosine or aniline blue. A series of preparations were shown in illustration and support of these statements.

Dr. Haycraft, of Sir Josiah Mason's College, Birmingham, maintained that the fibrils of striped muscle are homogeneous, and that the stripes are entirely owing to alternate convexities and concavities, which, with the stripes, disappear while the fibrils are stretched and their calibre rendered uniform.

This view was strongly opposed by Professor Rutherford.

The last discussion was on

THE VASO-DILATOR NERVES,

and was opened by Professor Morat. He described some researches made by Professor Dastre and himself, which led to the conclusion that there are vaso-dilator nerves, which, pass out of the spinal cord through the anterior roots of the second and third dorsal nerves (in the dog). They then, entering the sympathetic by the rami communicantes, pass up and supply the mucous membrane of the lips and hard palate and nose on the opposite side. Stimulation of their distal end causes dilation of the blood-vessels here.

Dr. Roy said that he had failed to find any vaso-dilator nerves in the spleen or kidney. He alluded to his discovery that the spleen is the seat of perfectly rhythmical contractions and dilatations, and that in the case of the kidney, effects are produced upon the renal circulation by drugs introduced into the blood, even after division of all the nerves going to the organs.

---

## SECTION ON MILITARY SURGERY AND MEDICINE.

The Section commenced its work by considering the subject of the

ANTISEPTIC TREATMENT OF WOUNDS IN THE FIELD.

As the result of the discussion, certain very definite conclusions were reached. Professor Esmarch, Surgeon-General Mouat, V.C., Professor Longmore, and Dr. Casson, all agreed that strict Listerism, in-

volving the use of the carbolic spray, could not be attempted on the battle-field. Professor Esmarch stated that the chief object of the surgeon is so to treat the wound that no further harm may result to the patient during his transport to the dressing-station. Nevertheless, all agreed that the first dressing should consist of some antiseptic application, and various forms of dressing were recommended, capable of being carried in a small packet by each soldier on going into action.

At the next meeting, Professor Esmarch read a paper

ON THE TREATMENT OF INJURIES OF THE BLOOD-VESSELS IN THE FIELD.

He stated that all tourniquets should be replaced by elastic tubes, by which means effectual compression of the vessels could be secured until the wounded man be brought to the lazaretto.

Papers were also read on the

TRANSPORT OF SICK AND WOUNDED TROOPS IN TIME OF WAR.

Dr. Gori having made reference to the death of Dr. Otis, Surgeon-General Longmore referred to it in the graceful and feeling diction for which he is justly known. Dr. Billings replied on behalf of the Medical Department of the United States Army.

On Saturday, August 6th, the main discussion turned on the

ETIOLOGY OF ENTERIC FEVER IN INDIA.

The view of Surgeon-General Maclean, that enteric fever arises from pythogenic causes only, cannot be maintained. Surgeon-General Fayrer, Surgeon-General Hunter, and Dr. Norman Chevers, as the result of their unequalled experience, thoroughly disbelieve that all cases of enteric fever are due to filth causes and to a specific entity formed in the patient's body, but that there are unquestionably cases of atmospheric or climatic origin.

The subject for discussion on August 8th was the

INFLUENCE OF THE CONTAGIOUS DISEASES ACT ON THE PREVALENCE OF THE VENEREAL AFFECTIONS AMONG THE TROOPS SERVING IN THE UNITED KINGDOM.

The subject was dealt with chiefly from a statistical point of view. The paper on the subject was read by one so distinguished in statistics as Inspector-General Robert Lawson, and, as on all other occasions, the vast benefit of the Contagious Diseases Act, not only on the prevalence of all forms of venereal disease among the troops, but also among the civil population of the stations where the troops have been quartered, was abundantly proved. Thus, in comparing fourteen stations under the Act during the periods of 1861–66 and 1867–72, a marked diminution of the number of admissions into hospital in the latter period of six years, when the Act was in full force, was observable.

SUNSTROKE.

On the afternoon of the 8th, Sir Joseph Fayrer pointed out clearly the various conditions produced by the effect of the sun in tropical climates. These are chiefly three: simple syncope from exhaustion caused by heat; a condition analogous to shock due to the action of the direct rays of a powerful sun on the brain and cord; and overheating of the whole body from either the sun's rays or from the high temperature produced by them, causing high thermic fever. Concerning the grave prognosis in the latter condition, great stress was imposed. Grave structural changes are produced inevitably in the nerve-centres. The truth of this was testified to by Dr. Yandell, of America, Drs. Christie and Ewart, according to whose experience the character of the individual affected always became changed after so-called recovery. Mania and epilepsy also are most liable to follow, and the practical outcome of these facts was expressed in the opinion that no one who had ever had a real attack of *coup de soleil* ought to be allowed to return to India.

---

SECTION ON MATERIA MEDICA AND PHARMACOLOGY.

Dr. William Squire read a short paper on

BROMIDE OF ETHYL,

and Dr. J. Milner Fothergill on

STRYCHNIA AS AN EXPECTORANT.

In the subsequent discussion, Dr. Lauder Brunton said he could fully confirm Dr. Fothergill's statement that strychnia was a powerful stimulant of the respiratory centres, and he often employed it with success in the treatment of the night-sweating of phthisis. He considered that the pathology of the night-sweating of phthisis admitted of a very simple explanation. The respiratory centre becomes exhausted by reflex irritation from the lung, so that it no longer responds so readily as it should to the stimulus directly applied to it by carbonic acid in the blood circulating through the medulla and spinal cord. In consequence the blood becomes more or less venous, and to this venosity and the consequent imperfect tissue-change the nervous and muscular exhaustion and prostration observed as an accompaniment of night-sweating was attributable. When a dose of strychnia or nux vomica is administered at bedtime, the excitability of the respiratory centre is stimulated, so that any excess of carbonic acid increases its activity, and thus the accumulation of carbonic acid is prevented and the sweating checked. Picrotoxine is also a powerful stimulant of the respiratory centre, and this may explain the success which has attended its administration in the night-sweating of phthisis. The cases in which strychnia is specially indicated are those in which the cough is not so violent as to be distressing, and where the general debility and weakness of the circulation and digestion are prominent symptoms.

Professor Eulenburg's paper on the introduction of an

INTERNATIONAL PHARMACOPŒIA

excited great interest, and gave rise to an animated discussion, in which many visitors from the Pharmaceutical Congress took part. It was resolved to appoint a committee, consisting of two delegates from each country attending the Congress, to co-operate with the committee appointed by the Pharmaceutical Congress, with the view of taking such steps as might be necessary to draw up a scheme that would ultimately form the basis of an international pharmacopœia. At a subsequent meeting the following names were submitted for consideration, it being understood that the list was not final, and that it was incomplete: France, Dr. Dujardin-Beaumetz and Professor Vulpian, the Dean of the Medical Faculty of Paris; America, Dr. Wood, Professor Austin Flint; Prussia, Professors Liebreich and Rossbach; Holland, Professors Stokvis and Fokker; Switzerland, Professor Prevost.

Professor Plugge's paper on the

LETHAL DOSE OF DIFFERENT ACONITINES

gave rise to a prolonged discussion, in which M. Petet and others took part. There was a general consensus of opinion that the term aconitia, unqualified in any way, might mean anything or nothing. Some specimens were eight times as strong as others. The tincture of aconite, however, could be made of uniform strength.

In discussing the subject of the

NATURE AND LIMITS OF PHYSIOLOGICAL ANTAGONISM,

Dr. Wm. Murrell said that it was impossible to arrive at any definite conclusion or to obtain anything like precise information from observations made on man alone. It was difficult to distinguish between antidotism and antagonism. It was easy enough to arrest the tetanus of strychnia by paralyzing the motor nerves with curare, but this was not antagonism, for the two drugs acted on totally different structures. The great difficulty was to make absolutely sure that both drugs acted on the same part. This could only be done by working on substances consisting of protoplasm in one form only. The existence of antagonism, and even of mutual antagonism, could be shown by acting on cilia and alkalies alternately. But still more conclusive proof could be obtained by working with Roy's apparatus on the ventricles of the frog's heart. Many difficulties had been experienced in the use of this method, but since the introduction by Dr. Ringer of dried blood and saline they had been considerably lessened. Dr. Ringer had recently shown that a complete and mutual antagonism existed between chloroform and ammonia, and between iodoform and ammonia. Dr. Murrell then exhibited a series of tracings obtained with the same apparatus, and illustrating the mutual antagonism of extract of muscaria and atropia, and of extract of jaborandi and atropia. Some of these tracings were obtained with the whole ventricle, and to these objection might possibly be made on the ground that there was no absolute proof that the antagonism was exerted on identical structures, but other tracings were taken solely with the lower two-thirds of the ventricle which were known to be free from nervous ganglia, and to these the objection could not be urged, and they might be taken as absolute and positive proof of the existence of mutual antagonism.

Dr. William Squire's paper on

PILOCARPINE

contained nothing that has not long been the common property of the profession, but nevertheless gave rise to an interesting discussion. Dr. Jacobi, of New York, detailed at some length his experience with this drug in the treatment of diphtheria; and Professor Quinlan, of Dublin, who was the first to introduce jaborandi in Ireland, advocated its use in large doses. Dr. Henri Huchard, of Paris, said he had obtained excellent results in the treatment of diabetes, and also as a means of arresting the night-sweating of phthisis. In the latter case he regarded it almost as a specific. Mr. Martindale objected to a statement that had been made, that preparations of jaborandi, from their liability to contain a second alkaloid, jaborine, were less safe and less certain than pilocarpine. Pharmacists hesitated to accept the evidence that had been adduced in favor of the presence of this in true jaborandi.

The final meeting of the Section was opened by a long and interesting discussion on three papers bearing more or less on the same subject. They were on the "Action of Medicines upon the Heart and Blood-vessels," by Professor Boehm, of Marburg; on the "Action of Atropia and Muscarin upon the Heart of the Frog," by Dr. W. Gaskell, of Cambridge; and on the "Action of Duboisin on the Circulation," by Mr. G. A. Gibson, of Edinburgh. Dr. Murrell, after alluding to the different modes of investigating the action of drugs on the heart, expressed his surprise that Professor Boehm should have supposed that all anæsthetics had a similar action on the cardiac apparatus. Chloroform slowed the heart, and weakened, and finally arrested it in diastole; whilst ether quickened the ventricle, and exerted no paralyzing action. He was surprised, too, that no reference should have been made to the action of nitro-glycerine on the blood-vessels. Dr. Leech, of Manchester, gave some account of his experience with nitro-glycerine in the treatment of angina pectoris, and of certain observations he had made in a case recently under his care. Professor Rossbach, of Wurzburg, read a paper on "Papayotin." Dr. Jules Worms, of Paris, made a short communication on the "Action of Sulphate of Quinine in Glycosuria." After a vote of thanks to the President and secretaries, the proceedings terminated.

---

THE MUSEUM.

Living examples of rare or very interesting diseases were shown every morning during the meeting of the Congress, in a room adjoining the Museum, at 9.30 A.M.; and these demonstrations were largely attended, forming one of the most successful features of the Congress. We give below notes of some of the cases shown:

Dr. Duckworth showed a group of well-marked cases of true gout with uratic deposits, and Mr. Hutchinson, on the same day, showed several examples of the same disease and rheumatic arthritis, separately and in association. Messrs. Macnamara, Page, and Treves exhibited cases of joint disease in tabes dorsalis. Mr. Page's case was remarkable, for the joint affection (which involved the foot) was present together with the Argyll-Robertson symptom and absence of knee-jerk, but without any ataxy. The patient had had severe pains in the limbs and vomiting some time previously. Dr. Ord showed a number of cases illustrating myxœdema, illustrating the disease in various stages of progress. Dr. Barlow exhibited a case of aphasia, with right brachial monoplegia, in a boy, the subject of hereditary syphilis; Dr. Sturge some cases of muscular atrophy; and Mr. Hutchinson two cases in which rupture of the brachial plexus was diagnosed.

Two cases of osteitis deformans (Paget) were shown.

Case I., under the care of Mr. Frederick Treves. The patient was a woman, aged forty-nine. Five years ago she began to notice some sense of weariness in the legs on walking, and then discovered a "bending" of the left shin. The case now presents a typical aspect. The left tibia is enormously thickened, and bends forward and outward. The right femur is bent forward at its upper part, and is greatly thickened. The right tibia and left femur are but little affected. The spine is much curved in the upper dorsal region, and in five years she has lost four inches in height. The skull is enlarged, and presents a very characteristic outline. Of the bones of the upper extremities only one is affected, viz., the left ulna. The bone is much thickened, and

curved backward. The movements of the hand are, however, not impaired. The affection is perfectly painless, and the patient's general health good.

Case II., exhibited by Mr. Symonds, surgical registrar of Guy's Hospital. The patient, a widow, aged seventy. At the age of forty-nine the tibiæ began to curve and become prominent, next the femora. Twelve years ago the left radius began to thicken and twist, and now it is so much elongated and curved that the hand is fixed in a position of complete pronation. The head and spine are unaffected.

Two cases of dactylitis syphilitica (Taylor) were shown by Mr. Dawson Williams. Case I., under the care of Mr. Churchill. A male child, aged two years and four months; no history of syphilis to be obtained. Nearly all the metacarpal and phalangeal bones of both hands, the first metacarpal bones of both feet, and the upper ends of the radius and ulna on both sides, as well as the nasal bones, were affected with a chronic inflammation, which had persisted for about a year, and had in the hands, feet, and nose, advanced to the suppurative stage.—Case II., under the care of Mr. Walter Pye. A male child, aged one year and ten months; a distinct history of syphilis in the parents; the metacarpal bones and phalanges of one hand, to the number of five altogether, were affected, as also the upper end of the radius.

A case of varicose veins of the abdominal wall was exhibited by Mr. Frederick Treves. A lad, aged seventeen, was kicked in the lower part of the abdomen, by a horse ten years ago. Some months after he noticed commencing varices in the left leg; the condition gradually extended. Now the left internal saphenous vein is extremely varicose, and ends as a huge mass at the saphenous openings. The superficial epigastric and superficial circumflex veins of the left side are also very varicose. The vein that runs from the axillary vein to the femoral (described by Mr. Fenwick in the anatomical section) is very conspicuous. He has a double varicocele; no hemorrhoids; viscera healthy. It is difficult to understand where the obstruction exists, if there be obstruction. If in the vena cava, it is hard to perceive why the right leg should be quite sound; if in the common iliac vein, the double varicocele is mysterious.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 4, 1881, to September 10, 1881.*

CAMPBELL, JOHN, Lieut.-Colonel and Surgeon, Medical Director of the Department. Granted leave of absence for twenty days. S. O. 91, Department of the South, September 2, 1881.

THE LAST OF TYPHUS FEVER IN NEW YORK CITY.—At a meeting of the City Health Board, September 6th, Professor Janeway called attention to the fact that the last typhus fever patient had left the Hospital on Blackwell's Island, and that there was no more typhus fever in the city. It still exists in London and St. Petersburg, but unless it is brought to New York from those cities, there is no danger of an outbreak of it in New York next winter. From the time of the outbreak on the 21st of March last to yesterday, there were four hundred and ninety cases of typhus fever in New York. One hundred and twenty-one of these ended fatally.

THE DISCUSSIONS AT THE INTERNATIONAL MEDICAL CONGRESS.—We publish in this issue quite an extended report of some of the discussions at the International Medical Congress. The character of the men who took part, as well as the importance of the topics themselves, make these debates extremely valuable. We doubt if any portion of our reports of the Congress will be read with more profit or interest.

THE FATALITY FROM THE HEAT in this city last week was very great. The heat itself was something unprecedented, the thermometer rising on Thursday, the 8th instant, to 101° in the shade.

An unofficial and probably incomplete list of the cases of prostration or sunstroke from the heat during four days is as follows:

September 6th.—Six fatal cases of sunstroke.

September 7th.—Forty-four cases of prostration from heat and sunstroke.

September 8th.—Twenty-one fatal cases of sunstroke; fifteen cases of prostration from heat.

September 9th. — Eighteen fatal cases of sunstroke.

Total.—One hundred and four.

To this must be added an increased mortality among the children from diarrhœal diseases. The deaths September 7th were one hundred and twenty-four; September 8th, one hundred and sixty-eight.

TYPHOID FEVER FROM MILK.—A recent outbreak of a mild form of typhoid (?) fever in the Roman Catholic Orphan Asylum in this city, was ascribed to the poor quality of the milk furnished the children. An analysis made under the direction of the City Board of Health, by Dr. C. E. Munsell, gave the following result: Temperature, 60° F.; Lactometer, 109; Cream, per cent., 4; Water, per cent., 88.69; Fat, per cent., 2.64; Casein and sugar, per cent., 8; Salts, 68.

This showed that the milk was skimmed, and probably watered.

The milk-dealer was arrested, but was discharged, says Dr. Munsell, through political influence.

AMERICAN ACADEMY OF MEDICINE.—The sixth annual meeting of this association will be held in New York on Tuesday, September 20th, at 3 P.M.

AMERICAN GYNECOLOGICAL SOCIETY.—The annual meeting of this society will be held at the Academy of Medicine, 12 West Thirty-first street, September 21st, 22d, and 23d. Morning session at 10 A.M.; afternoon session at 3 P.M. The profession of this city and vicinity are invited to attend.

## THE TREATMENT OF DOUBLE TALIPES EQUINO-VARUS BY OPEN INCISION AND FIXED EXTENSION.

By A. M. PHELPS, M.D.,
CHATEAUGAY, N. Y.

*Mr. President and Gentlemen of this Society:* As a delegate from Franklin County Medical Society, I came to Albany expecting to take no part in the proceedings of this meeting only so far as the duties of delegate might devolve upon me. Since my arrival I have been urged by professional friends, to whom I had previously sent photographs, to report the case at this session of a little patient suffering from double talipes equino-varus, upon whom I operated by open incision and fixed extension.

The case was a little girl, six and a half years of age. I first saw her May 15, 1880. The feet were very rigid. The inner side was very much shortened, and described a sharp curve from the heel to the great toe, which rested upon the inner side of the tibia when the weight of the body was put upon them. The attempt at walking had produced large bunions upon the dorsum of the feet, which were very much inflamed. The head of the astragalus was subluxated forward, and the limbs were very much atrophied.

FIG. 1.

Fig. 1 is taken from the photograph presented to the Society, and gives a correct idea of the extent of deformity.

Under an anæsthetic, and assisted by my friend, Dr. Farnsworth, and my student, Mr. Van Vechten, I divided subcutaneously the tendo achillis, tendon of tibialis anticus, the plantar fascia, and such contracted tendons and bands in the soles of the feet as I could safely do without wounding the artery and nerve. The feet were imperfectly restored to their normal position, and dressed with Sayre's temporary dressing (see Sayre's "Surgery," p. 98). After the wounds had healed, and upon the seventh day, Barwell's dressing with rubber muscles was adjusted to each limb, and faithfully continued for two months. Manipulation, showering of the limbs, and strychnia hypodermically were used daily. Circumstances prevented the use of electricity. July 25, 1880, the feet had not improved since the operation in May, and showed a determination to relapse when the dressings were removed.

Dr. Alfred C. Post, of New York, who was in Chateaugay a short time before, related his treatment of a case of torticollis, in which he made an open incision, and divided all contracted parts upon a director, thus securing a thorough operation without the danger of wounding important blood-vessels. The case, after some thought, impressed me as being something new and thoroughly scientific. By referring to authorities, I found no mention made of an operation upon club-foot by open incision. Sayre advises the division of the skin when it offers resistance to the foot being extended to its normal position. So, with no little hesitancy, I decided to operate upon my case by open incision, and dress the foot in a normal position, and keep it there until it healed. Under an anæsthetic, and assisted by Dr. Farnsworth, I made an incision half an inch in front of the ankle-joint, extending across the inner side of and two-thirds the distance across the soles of the feet, through the skin and cellular tissues. Each contracted part was now carefully divided as it showed itself, when the parts were put upon the stretch by extending the feet. After the completion of the operation, it was found that the incision had been carried down to the bone in both feet. The artery and nerve were both divided in the right foot accidentally; but in the left they were carefully guarded. The long calcaneo-cuboid ligament was not divided, as it offered no resistance; otherwise it would have been cut. The tendo achillis was divided subcutaneously. I would suggest the use of an Esmarch bandage in all cases of the kind. The wounds were dressed daily with balsam Peru and oakum, and the feet kept extended upon a foot-rest which I devised for the purpose. A glance at the cut will furnish a correct idea of its construction.

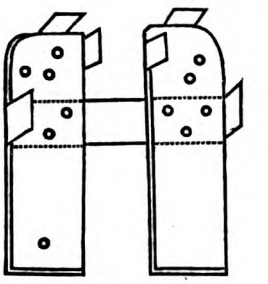

FIG. 2.

It consists of two boards the length and width of the foot, a little narrower at the heel than at the toe, screwed upon a plate of band iron, one and a half inch wide and ten inches long, the ends of which are turned up, projecting two inches above the board and just in front of the external malleolus. Another piece of the same iron is attached behind the inner malleolus. A leather loop is fastened at the end of the board, through which a bandage is passed and carried over the instep, to prevent the foot from slipping back. The board and projecting irons are carefully padded. A few turns of a roller-bandage secures the heel between the two fixed points. Now the bandage is carried over the instep from without *in* under the board; then between the board and foot from without *in*. Turn the bandage back over the foot from within *out*, and the toes can be drawn outward to the desired extent, the foot being used as a lever between the fixed iron points.

The wound healed entirely in three weeks. The

board was worn for fourteen weeks, which I think was unnecessary, the patient using crutches.

Three times a *delicate point* of nitrate of silver was drawn through the bottom of the wound, which gaped one and one-half inch. This prevented the growth of granulations at the bottom of the wound, and allowed healing to take place from the sides by the skin gradually crawling downward into the wound. By this process, and keeping the feet constantly extended, the inner and shortened side was lengthened nearly an inch. The feet were flexed upon the legs by cords passing from the end of the board to strips of adhesive strap secured to the legs.

FIG. 3.

Fig. 3 is from the photograph showing the result of treatment, taken fourteen weeks after operating.

After photographing, a Sayre's shoe was put upon the right foot, and an ordinary shoe with a stiff counter upon the left. The muscles are rapidly developing, and sensation is perfect in both feet. The patient can walk rather awkwardly without shoes, the feet showing but little tendency to relapse. The theory that a cicatrix invariably contracts, drawing the parts to their original deformity, has, I think, been demonstrated by Dr. Alfred C. Post, of New York, to be incorrect. In his paper upon deformities from burns, read before the State Medical Society, the doctor proves that if the parts divided be kept upon the stretch until thoroughly healed, the cicatrice will not contract and reproduce the deformity. If this is an established fact, and I think it is, why may we not lengthen the contracted side of a club-foot by keeping it constantly extended after a free incision? In this patient I am sure that I did. The result in this case and others with which I have had to do has led me to arrive at the following conclusions:

*First.*—That division of deep structures lying contiguous to important blood-vessels and nerves should be performed by careful open incision.

*Second.*—That, in all cases of varus in which there is a decided shortening of the inner side of the foot from the contraction of the tissues, free division of the contracted tissues by open incision and fixed extension of the parts is the shortest and most satisfactory route to a cure.

*Third.*—That all cases of varus should be at once extended as nearly as possible to the normal position before any appliance whatever is put on them.

*Fourth.*—When, by manipulation and a reasonable amount of force and time, the foot cannot be extended to a normal position, more can be done in five minutes with a scalpel or tenotome than can be accomplished in weeks, and often months, by all the appliances known to surgery.

---

Since reading the above paper, I have operated upon another case—a little boy, seven and one-half years old—suffering from an extreme equino varus of the right foot.

Fig. 4 shows the foot before and twenty-eight days after the operation. The astragalus was subluxated forward, making a serious deformity. A large and painful bunion had formed over the metatarso phalangeal articulation upon the dorsum of the foot, marking the point upon which rested the weight of the body during locomotion. All tissues excepting the artery and nerve and long calcaneo-cuboid ligament were cut. It was with great difficulty that the subluxation of the astragalus was reduced after the incision was made. Each step of the operation and after-treatment enumerated in the case of the little girl was followed in this case.

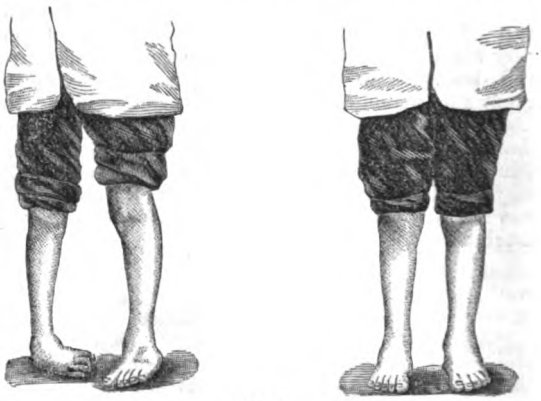

FIG. 4.

The wound, which gaped one and one-half inch, and extended to the bone, was entirely healed by the fourth week. At this time an ordinary shoe with a stiff counter was put upon the foot, and the little fellow runs about, the foot turning outward and being nearly free from deformity. I find that the cicatrice is somewhat sensitive, and has contracted but little. The inner side of the foot is materially lengthened. The atrophied muscles are fast regaining their normal tone and size. I had the pleasure of exhibiting this patient to Dr. Alfred C. Post, of New York, who was called to this village just twenty-eight days after the operation, and a day or two after putting on the stiff shoe. As to the extent of deformity, age of the patient, mode of operating, duration of treatment, and general result, I think he will verify every statement made. In a letter bearing date April 30, 1881, the doctor says:

"You are at liberty to say that I have seen your patient upon whom you operated for talipes by open incision, and that I regard the result as a very remarkable success."

In another letter, dated June 14, 1881, he says:

"I have operated on two cases of talipes equino-varus by open myotenotomy. The first case was that of a child eight months old. The degree of the deformity, and the rigidity of the parts involved were such as I do not recollect to have seen before in so young a child. I divided the skin, the plantar fascia, the flexor brevis digitorum, the flexor longus, flexor accessorius, tibialis posticus, flexor longus

hallucis, flexor brevis hallucis, abductor hallucis, etc. Having secured the vessels, I drew the foot nearly to its normal position, and filled the wound with picked lint dipped in carbolized oil, ten per cent. I then applied adhesive plaster and bandages, holding the foot nearly in its normal position. I omitted to state that I made a subcutaneous division of the tendo achillis. I performed the operation on May 7th, and on June 11th the wound was healed, and the foot, when bandaged, was brought into a position of slight flexion and abduction—that is, not only as far as the normal position, but a little beyond. The result was satisfactory in the highest degree. No tractile force was employed except normal extension, followed by a roller-bandage and strips of adhesive plaster. The second case was that of a little girl two and one-half years old, under the care of Dr. Jacobi at Mount Sinai Hospital. Dr. Jacobi requested me to operate, and I did so, following substantially the same course as in the former case. The case is not under my own care, and I have not been able to follow it up closely; but it is, on the whole, doing well."

---

A VETERINARY MEDICAL REGISTER.—The *Journal of Comparative Medicine* has had compiled, for the use of its readers, a veterinary medical register. It contains about nine hundred names of veterinary surgeons, living in different parts of the United States.

This is the first effort that has ever been made to make such a compilation, and the work reflects much credit upon the enterprise of the editorial staff. In commenting on the comparative condition of veterinary and human medicine, the editor says:

"There are in the present Register eight hundred and ninety-eight names. We do not think that the total number of regular veterinary surgeons in this country greatly exceeds this. Of these there are, as nearly as we can estimate, not over two hundred veterinarians who have received a medical degree. The rest have picked up what knowledge they could in various ways, and have then assumed the title. Their education and professional skill is necessarily far below what could be desired.

Now, on the other hand, there were in this country in 1878, 120,000,000 domestic animals. A very low estimate of the value of these is $2,000,000,000. This does not include dogs, hens, and other smaller domestic animals and pets. The annual loss among all these creatures from various diseases and injuries is simply immense.

From one disease alone, hog cholera, there has been an annual loss of, it is estimated, $200,000,000. Devastating epidemics are likely to break out any year.

The loss to exporters on account of pleuro-pneumonia was, in one year, about $2,250,000.

We place these vast moneyed interests on one hand, and the very small number of educated veterinarians, who form an important element in protecting them, on the other. The necessity for more skilled practitioners is apparent, and is, indeed, a crying one.

It is estimated that there are nearly twice as many physicians in this country as are really needed.

There are, on the other hand, probably not one-twelfth as many fairly good veterinarians as our commercial and agricultural interests require, or as our sympathies with brute suffering should demand."

## AN INSTRUCTIVE EXPERIMENT.

BY GEORGE M. STERNBERG,
SURGEON U. S. ARMY.

NOTWITHSTANDING the researches of Pasteur,* as the result of which he announced, as long ago as 1862, that the alkaline fermentation of urine is due to the presence of a micrococcus, and the subsequent experiments of Lister, showing that, with proper precautions to exclude micro-organisms, urine drawn from the healthy human bladder may be kept indefinitely, freely exposed to the atmosphere, without undergoing any change, the chemists and physiologists have, perhaps, not yet generally conceded that this is *un fait établi*, and it is doubtful whether the full significance of this and similar discoveries has reached the understanding of a majority of the busy practitioners of medicine in this country.

The following experiments, therefore, which give very definite support to the assertions of the authors named, may not be without interest to the readers of the MEDICAL RECORD.

Having repeatedly demonstrated the presence of micrococci at the orifice of the male urethra, and knowing from Lister's experiments that urine, as contained in the healthy bladder, is free from bacterial contamination, it occurred to me that, perhaps, in passing urine from a full bladder, the first portion of the stream might wash away detached epithelial cells and bacterial organisms (see Fig. 2), so that the

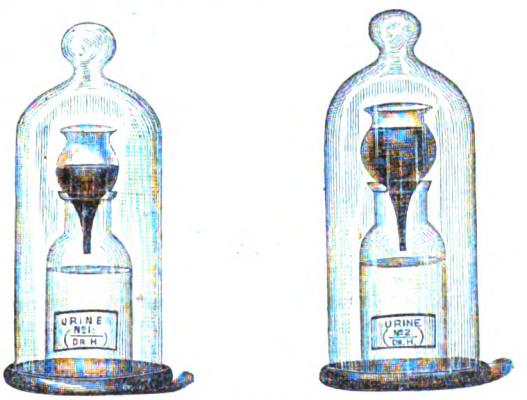

FIG. 1.

last portion, being received in a sterilized flask, would give evidence of freedom from these organisms by remaining unchanged; accordingly I made the following experiments:

*Experiment No.* 1.—Biological laboratory, Johns Hopkins University, Baltimore, Md., June 25, 1881.—Two bell-shaped cups were sterilized in the flame of a Bunsen burner, and placed under clean bell-jars, resting upon ground-glass plates, as shown in Fig. 1. (This is Lister's apparatus slightly modified.) These glass cups, having a stem drawn out in the flame, are more easily sterilized by heat than a wine-glass, which was used by Lister. They may be held in the flame of an alcohol lamp and introduced under the bell-jar while still so hot that any organism coming in contact with them would be destroyed.

They are supported by wide-mouthed bottles. This apparatus being ready, I desired my assistant, Dr. H——, to pass a small quantity of urine in No.

* Ann. de Chimie et de Physique, No. 62, p. 52, 1862; Comptes Rendus, Académie des Sciences, lvii., p. 210, 1864.

1 from the first portion of the flow, and in No. 2 from the last, removing and replacing the bell-jars as expeditiously as possible.

*Result.*—June 30th. No. 1 contains a considerable deposit, is turbid, and decidedly alkaline. No. 2 remains perfectly transparent, has no rudimentary deposit, and is acid. No. 1 contains an abundance of micrococci, which are shown magnified 1,000 diameters, in Figs 3. and 4, which are from photo-micrographs made from specimens obtained from this very experiment. No. 2 is free from organisms. A single drop taken up from the bottom of No. 1, by means of a pipette, was allowed to fall in No. 2. The following day No. 2 was turbid, had an alkaline reaction, and contained an abundance of *micrococci ureæ*. This experiment cannot be expected to succeed in every instance, as the complete washing away of organisms by the first portion of the stream may not occur, and it is possible that the urethra might have been washed out at the previous passage of urine, so that the first portion passed would be free from organisms, while the last might be contaminated by the detachment of epithelium, in which micrococci were imbedded, as seen in Fig. 2.

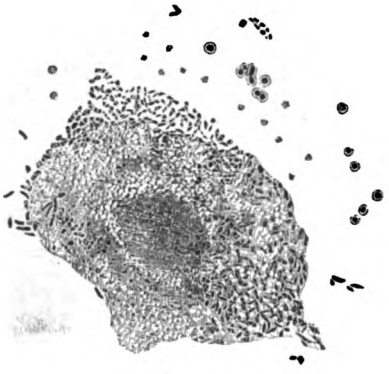

FIG. 2.

Some such explanation seems necessary to account for the result obtained in the following experiment.

*Experiment No.* 2.—Baltimore, August 1, 1881.—The above experiment was repeated, with the same precautions.

*Result.*—August 11th.—No. 1 remains acid and transparent in the upper portion, but the lower third is occupied by a loose, finely granular deposit, such as is often seen in fresh urine immediately after cooling (this deposit was noticed soon after the commencement of the experiment, and underwent no apparent change). No. 2 has an alkaline reaction—a film of urate of ammonia upon the surface, and contains an abundance of *micrococci ureæ* in the copious deposit at the bottom of the cup.

*Experiment No.* 3.—Baltimore, Md., August 1, 1881.—Four sterilized cups were prepared as in the previous experiments, and into each was passed a little urine from my own bladder, after first taking the precaution to disinfect the extremity of the urethra. This was accomplished by the liberal use of a three per cent. solution of carbolic acid, which was applied by means of a pledget of asbestos held by slender forceps. The asbestos was first sterilized in the flame of a Bunsen burner, and then being dipped into the disinfecting solution, was repeatedly and thoroughly applied to the mucous membrane to the depth of half an inch, or a little more. This operation produced some pain, and a little soreness upon passing urine was felt for two or three days.

*Result.*—Five days after (August 6th) the urine in all the vessels remained transparent. At this date No. 3 was inoculated with organisms from the mouth of the urethra. This was done by twisting around in the orifice of the urethra a small ball of asbestos, previously sterilized by heat, which was then dropped into the cup containing urine (No. 3), the bell-jar being removed for an instant only for this purpose. Five days later the contents of the four cups were carefully examined. Nos. 1, 2, and 4 remained transparent and acid; No. 3 was alkaline, and contained an abundance of *micrococci ureæ*.

By reference to the figures (at least as shown in my photo-micrographs—how successfully these may be copied I cannot say at this writing), it will be seen that the micrococcus shown in Fig. 2 differs somewhat in appearance from that shown in Figs. 3 and 4. The specimen from which the first was

FIG. 3.

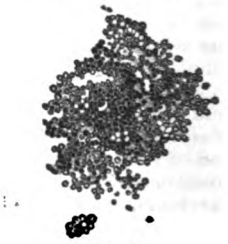

FIG. 4.

taken was obtained by applying a thin glass cover directly to the mucous membrane at the extremity of the urethra, which was everted by slight pressure, while the others, as already stated, are from urine which had undergone the alkaline fermentation.

By the little operation above mentioned I have always been able to obtain an abundance of micrococci, scattered or adherent to the surface of epithelial cells, from the mouth of my own urethra or that of others.

It must be remembered, however, that the use of high powers and proper staining fluids is necessary for their satisfactory demonstration. The photo-micrographs, from which these figures have been copied, were made with a Zeiss $\frac{1}{18}$ in. hom. ol. im. objective, and the organisms were stained for photographing with a solution of aniline brown.

The difference in size and grouping, to which attention is called, may be due to the fact that this organism, under different circumstances, assumes a different appearance, and that the form taken when upon the surface of a mucous membrane freely exposed to the air is seen in Fig. 2, while that assumed when it is submerged in a liquid having the composition of urine is seen in Figs. 3 and 4. It is possible, however, that we have here two different organisms, and that the *micrococcus ureæ* is less abundant than the form seen in Fig. 2, and that it consequently escapes attention. This is a question to be settled by future experiment.

NITRITE OF AMYL IN CHORDEE.—Nitrite of amyl will be found a very effectual remedy in chordee and painful priapism. We have recently prescribed it for those conditions with very satisfactory results. Three to five drops, by inhalation, is the proper dose.—*St. Louis Clinical Record.*

# CLINICAL STUDIES OF INEBRIETY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

I PROPOSE to group some cases of inebriety which have come under my care, with the object of showing certain causes and conditions that have never been studied or recognized.

I do this in the form of clinical reports and outlines, with no attempt to be exhaustive, but rather to indicate fields of inquiry which can be studied in the practice of almost every physician. I approach this subject from a physical standpoint, and recognize in every case of inebriety a pathological as well as a psychological condition. The persistent or paroxysmal use of alcohol in toxical doses for toxical effects always indicates disease, whether we recognize it or not. In some cases this disease has begun long before alcohol was used; in others, alcohol has merely kindled into activity and fixed certain latent tendencies to inebriety; in all cases alcohol produces perversions and degenerations of every tissue of the body, and intensifies every abnormal condition that may be present. Also, every case follows some general line of progress, more or less uniform, which can be traced, in most cases, from certain definite causes. No case of inebriety can be called accidental, but is always the result of some special conditions, which may be unnoticed at first, insidiously passing through long years of an apparently formative stage, then bursting out, like a fire that has been smouldering, with an intensity that is both alarming and mysterious. A careful grouping of the history and symptoms of these cases furnishes unmistakable evidence of their curability, properly treated in the early stage of the disorder. Recently a condition called alcoholism has been described by many writers, who have asserted boldly that the general symptoms grouped under this term comprised the whole subject. Such views are not supported by any clinical history of cases, and are evidently based on the most imperfect studies of certain chronic conditions, which may or may not follow directly from alcohol. Hence, the term alcoholism as used at present does not describe cases of inebriety.

I wish to indicate in the following cases certain general conditions of exhaustion which react in inebriety with increasing frequency every year, beginning in functional changes and perversions of nutrition, and soon manifesting themselves in disturbance of the nerve-centres and loss of balance between waste and repair. After passing a certain limit it develops into some particular form of disorder depending upon unknown conditions. In these, and many other cases which I have noted, inebriety seemed to follow the medicinal use of alcohol given for this exhaustion. The alcohol, acting as an exciting cause, determined the form and nature of the disorder.

I think it will be clearly seen from further studies that there are certain conditions of neurasthenia which have a special tendency to break out into inebriety from the slightest exposure or use of alcohol. It is evident that alcohol, given for any length of time medicinally in cases of defective brain and nerve organizations, or in general impairment of nerve vigor and strength, is exceedingly dangerous, and likely to develop into inebriety.

In these cases there is often an unknown element or causation, which can only be understood by a careful study of all the conditions and surroundings, and a natural history of the patient.

CASE I.—*Inebriety from Exhaustion arising from Sexual and Dietetic Excess—Recovery.*—H——, born of healthy parents, on a farm, and after a vigorous boyhood, with a good common-school education, he came to the city as a clerk. He was correct and industrious in his habits, and in due course of time became partner, and finally, at forty-eight years of age, was a wealthy, prosperous merchant. He was married, perfectly temperate, gave strict attention to business, seldom going away for recreation. His business went on methodically, and with but little change from year to year. He had no special pleasures or interests outside, attended church regularly, went to the theatre occasionally, and seemed living a most temperate, healthy life. At this time he complained of sleepless nights and deep depression in the morning, found that his hands trembled after writing much, and a feeling of exhaustion followed any muscular exercise. He had every appearance of health, although his appetite was changeable and capricious. By the advice of his physician he went to Europe for six months, and returned with all these symptoms exaggerated. He was irritable and exhibited emotional disturbances, complained of dyspepsia and pains down the spine. An eminent physician was called in counsel, and general hyperæmia of the brain was diagnosed. After a few months of unsatisfactory treatment, another physician was called, and he urged generous diet, with large quantities of wines and old spirits. The result of this treatment was satisfactory, as nearly all the older symptoms disappeared, and he became an ardent advocate of the use of spirits as medicine. A few months later he became intoxicated, and quite violent for a time, and at last he was stupid every night from this drug. A new set of symptoms came on, which the attending physician affirmed were premonitory of ataxia. Another physician diagnosed alcoholism, and urged him to stop the use of alcohol. This was accomplished by substituting opium for the spirits, and when this was taken away chloral followed; then the long list of bromides and other sedatives were given, and finally he discharged all physicians, and began to use patent bitters, travelling to different mineral springs, and consulting quacks and any one that he imagined could relieve him. He suffered from loss of memory, excessive trembling, fear of death, muscular debility, and impulsive craving for spirits to relieve an undefinable sensation of weakness all over his body. His wife died at this time, and he came under my care. I found him using brandy, morphine, and chloral, the former constantly, the two latter irregularly, for every pain or disturbance that he detected in his case. He was suspicious, morose, excitable, drank milk constantly, and was full of petty whims; had dyspepsia, enlarged liver, disordered sensibility and motor functions. Advised with much clearness about his business, talked wisely about his own case at times, and was very urgent to give up the use of stimulants.

The treatment the first month after admission to hospital was principally baths and central galvanization, with powdered bark and phosphoric acid, as a tonic; massage, exercise, and regulated diet, with the mental stimulus of restraint, and rigid regularity in all the functions of every-day life, which was followed by rapid recovery. At the end of four months he went back to the city and arranged his business, and went out to live on a farm, under the care of a local

physician, who reports to me that he is now (two years later) in good health and spirits, only at times suffering from depression; that he is strictly temperate and careful of his diet; also that when he goes to the city on business, he comes back in great fear that he will be sick from the unhealthy conditions of city life.

This case was one of inebriety from exhaustion, and it would appear to the general physician to follow from close confinement to business, over-work, and perhaps bad conditions of living. The real history of failure of the ordinary functions of life was traced to excessive eating and sexual intercourse, extending over many years, with general neglect of all efforts to keep the mind in healthy activity by diversion.

Both mind and body had lost their elasticity, and inebriety followed most naturally, because it marked the real condition of exhaustion, and brought relief to many of the early symptoms. The mistake of prescribing stimulants for such a case merely precipitated what would have followed sooner or later. In his search for remedies for relief, alcohol would have been found and used in some form.

CASE II.—*Inebriety from Exhaustion and General Impairment of the Nervous Structure—Partial Recovery, Relapse, and Death.*—B——, a healthy, strong, vigorous clergyman in appearance, was admitted in 1879, with the following history: Both parents healthy, and no history of inherited disease in any member of the family. Was educated at Yale College, and entered the ministry at twenty-four years of age. He was stationed in a small country village, and spent but little time in study or visiting, but devoted great attention to the cultivation of plants and trees. At this time he was in good health, very temperate, and of quiet, reserved manner. Two years later he suffered from indigestion, and soon after began the study of foods and bathing. On this subject he entertained the most extravagant views, and carried them out in every-day life. He believed that the minimum quantity of grain food that would satisfy the appetite would promote longevity, and that bathing twice or three times a day was also essential. Other whimsical notions as to kind and quality of food entered into this theory, until at last he weighed and calculated every ounce of food and drink that entered his body. This continued for several years, impairing both his mind and body. Then he suddenly changed and became a gross eater and neglected to bathe. From this time he grew more indolent, and complained of nervousness, inability to sleep at night, great agitation during a thunderstorm, headache, exhaustion, and began to use bitters containing a large quantity of alcohol for relief. During a short journey on the railroad he was violently agitated by an accident which threatened to be very serious. The effects of this shock continued for several days, when he became intoxicated for the first time. A physician was consulted, and various remedies suggested and adopted without any results. For two months he remained in bed complaining of weakness, and drinking all the time freely of brandy and water. Finally he went abroad for a year, and returned worse than before. Two years of secret drinking and change followed; then he was brought to our care. His mind was full of delusions of persecutions, and a slight degree of aphasia was present; at times he reasoned clearly about his case, then seemed confused and talked about the exaggeration of his symptoms as seen by his friends, and his ability to recover if left to himself. He proved to be a very troublesome patient, seeking every opportunity to procure spirits, and was generally untruthful in all matters pertaining to himself.

Three months later he went away much improved, and began to supply a pulpit in the West. A year after he was taken to the City Hospital at Cincinnati and died from pneumonia. He had evidently been drinking for some time before.

Here the exhaustion had in all probability impaired the nervous structure, or so much weakened it that the violent shock from an accident permanently destroyed the equilibrium and the elasticity to recover again. His long-continued starvation diet, followed by the opposite extreme, led directly to inebriety. In both of these cases, even after inebriety had begun, the real causes were not recognized, and the usual element of vice was supposed to complicate and enter into the causation.

CASE III.—*Inebriety from Exhaustion—Not Recognized—Long-continued Medication—Recovery.*—A——, a successful banker, who came from the country when a boy, and through energy and temperate living had worked his way up to wealth and a position of great trust. He could give no history of inherited disease, and had lived carefully, avoiding all excesses, except late hours, all his life. When past forty and in easy circumstances, he spent most of his time at the club, playing billiards from nine in the evening to midnight and after. Often he indulged in a game supper before going home. He had for more than twenty years rarely gone to bed before midnight or after, and had eaten heartily in the early part of the evening, also smoked quite freely up to retiring. At about forty-six he began to complain of confusion of memory and thoughts coming and going momentarily, followed by depression of spirits and a general feeling of exhaustion. This increased to periods of trembling and unusual anxiety about minor matters. Extreme wakefulness at night, and a drowsy feeling through the day. A noted specialist thought symptoms of organic brain disease were impending, and advised alcohol and liberal diet, with rest from business. Three months of this treatment was followed by an abatement of some symptoms, and the appearance of others. He could not sleep unless using a large dose of spirits before retiring, and frequently he was under the direct influence of this drug. His mind had grown more dull and cloudy, and he was extremely irritable at times. His manners had changed, and he was changeable in his business habits, doing many things in a strange, unusual way. Other physicans were called in counsel, and in addition to many prescriptions a journey abroad was urged. In company with a physician he spent six months travelling, and returned with no improvement, but more confirmed in his alcoholic impulses. Another year of trial of remedies and different methods of treatment for various nerve-affections ended in disappointment. He was now using alcohol to intoxication nearly every day, and yet no one thought that this was a cause, or was of any influence, except to diminish the intense pain he claimed to be suffering from. On his way to Boston to consult physicians, he was taken off to spend the night in Hartford, and came out to see me, finally concluding to remain a few weeks. His physician wrote me a full account of his case, as one of general softening of the brain, attended with intense hyperæsthesia, for which alcohol alone caused relief. He urged that I continue the spirits by all means, as it would be perilous to drop them. The patient's

mind was filled with many delusions and a most remarkable dread of death and desire to live. His mind was also very acute in some things, and decidedly hysterical. By a little management the alcohol was withdrawn without his knowledge, and gradually all the acute symptoms subsided. Four months after he went away recovered, and spent the following winter in the country, improving steadily. At this time (a year and a half later), he has resumed his business, is a strictly temperate man, retires early and eats carefully, and gives much promise of permanent restoration. He has periods of depression yet, but by means of the Turkish bath and rest recovers quickly. His mind is good and he seems perfectly well.

This case is a very significant one, and represents a large class that can be found in nearly all business centres. The origin is perfectly clear, arising from irregularities of food and sleep; not over-work, but over-eating, and general neglect of all the healthy functions of the body. Lack of sleep, or sleep at irregular hours, will sooner or later impair the nerve-centres, and a long train of symptoms will follow, for which rest and diet, in most cases, will be all-sufficient. Alcohol may and will frequently relieve many of the symptoms following such excesses, but always at the peril of kindling a new disorder of the central nerve plexus, masking the real condition, and making recovery almost impossible. These cases almost always discover in alcohol a means of relief. For years I have urged that general exhaustion from excesses of any kind was the natural starting-point of inebriety. In dietetic and sexual excesses are often seen intimations of the approach of inebriety that cannot be mistaken. Other neuroses may supervene, or acute affections develop into chronic diseases, but the predisposition to inebriety seems to be present always.

Case IV.—*Inebriety from Nervous Strain and Exhaustion.*—E——, a lawyer, thirty-four years of age, temperate, and of healthy ancestry, living a quiet life, was unexpectedly elected to a responsible office. He worked hard, and was subject to much excitement and annoyances. He suffered from a short attack of fever, not well defined, for which he was given spirits freely. On recovery he continued to use alcohol, and one year later he was obliged to resign from office for inebriety. The mental strain and continuous excitement following the changed conditions of life when in office brought on exhaustion, which culminated in some form of fever, and the alcohol at this time gave form and direction to the neurosis. This case is now a confirmed inebriate, and has been repeatedly in jail for intoxication.

Case V.—*Inebriety from Irregular Food and Bad Nutrition, with Exhaustion.*—F——, a merchant of healthy parentage, temperate, and living a regular life, failed at thirty-two, owing to the bad management of his partners. Soon after he became a travelling agent for a manufacturer, and shared the profits of his work. For the next ten years he worked incessantly night and day, accumulating a large property. He travelled at night, and worked during the day, neglecting sleep, but he was very regular in eating. At forty-three years of age he could not sleep at night, had attacks of extreme restlessness, was very sensitive to noises, suffered from hyperæsthesia of the scalp and arms, and various digestive troubles, for which he was treated, generally with no benefit.

Finally he began to use bitters, and found relief. Then he became intoxicated from them, and at last drank whiskey every day, or bitters as he could procure it. Within a year he was a confirmed inebriate, and came under my care. I found him suffering from delusions of persecutions, extremely irritable, paroxysms of trembling, and sleeplessness at night. He complained of feeling exhaustion on the slightest exertion, and a sinking depression in the precordial region. Like all other cases, he was untruthful, impulsive, and needed strict watching, but after four months' treatment went away to live with his brother in Canada, who was a farmer. One year later he is in good health and has not used alcohol in any form. He is now buying country produce for a New York house, is very careful of his health, and works with great regularity, avoiding all excitement, either mental or physical.

The causes in this case were clearly exhaustion from irregular living, lack of sleep, and over-work. This exhaustion became more profound, until finally alcohol was taken to relieve it; then inebriety followed most naturally.

The following notes of other cases are given as supplementary, and as more fully exhibiting some of those conditions of exhaustion that are not studied or recognized at present.

Case VI.—An Irish laborer, with an obscure family history, but perfectly temperate for a period of five years while in the employment of a merchant, was severely stunned by a thunderbolt, and began to drink to excess. Complaining of general exhaustion, was sent to an insane asylum for mania from drink. Recovered and relapsed, and is now a chronic inebriate.

Case VII.—A healthy, temperate clerk was implicated in a till robbery; was intensely mortified and depressed, and was given whiskey at the jail quite freely for ten days. Was acquitted, but regularly, from this time, drank to excess.

Case VIII.—A railroad conductor, with good family history, who had been on the road twenty years and was overworked, but never drank anything. He was changed to a night-train, and soon after drank regularly, and then to intoxication; was discharged from the road, and is now a chronic inebriate. The strain from the changed work broke out into inebriety.

Case IX.—A mechanic, with a marked history of neuroses in his family, a temperate, hard-working man, lost his property by fire, and began to use beer, which soon culminated in stronger alcohols and inebriety. He died of pneumonia, superinduced by spirits, two years after.

Case X.—A young, nervous son of a farmer, with a history of insanity in the family, was employed as clerk in a drygoods house, with long hours and hard work. He boarded at a poor place, for economical reasons, was ill-fed, frequented bar-rooms, became an inebriate, and is now a chronic case.

Case XI.—A healthy farmer went into the drug business, was very ambitious to succeed, but failed and began to use quinine as a stimulant, then different forms of alcohol, and finally became a confirmed inebriate.

Case XII. was a physician of neurotic temperament, with a history of consumption and inebriety in the past generation. Was very prosperous, and by inheritance became the possessor of large wealth. He gave up healthy living and plunged into all kinds of pleasure, although not drinking. Six months' travel in Europe developed inebriety, and he is now a confirmed inebriate.

Case XIII.—A lawyer who had been on the bench for twenty years, and was much exhausted by over-

work, was advised by his physician to go abroad and to eat as much as he could, also to drink freely of wine. He returned in one year a periodical inebriate, and died two years after from excessive drinking.

Case XIV.—A farmer, suffering from malaria, was greatly depressed at the bad conduct of his son, who was sent to jail for theft. After two sleepless nights he began to drink alcohol to excess, and became an inebriate. He had been a healthy, temperate man up to this time.

These cases clearly originated in conditions of exhaustion, and the use of alcohol developed inebriety most naturally. Other forms of neuroses frequently follow, evidently dependent on causes that are unknown. The fact is well established that inebriety follows as a sequence in an increasing proportion of cases where physical and mental exhaustion are present. These neurasthenic cases cannot bear alcohol as a remedy in any form, without great danger. Any treatment of such cases which involves irregularities of living, food, or the use of wine, as in travelling abroad, is almost sure to develop inebriety.

A thorough study of these cases will often indicate the methods of treatment and the possibility of permanent cure.

## ANEURISM AND RUPTURE OF THE AORTIC VALVE.

By THEO. A. WEED, M.D., L.R.C.P., London,

CLEVELAND, O.

I was called, on August 18, 1880, to see H. J——, a clerk, aged thirty, fairly nourished, never had rheumatic fever. Always able to do his work, although he has suffered much from palpitation for the last eight years. Four months previous to the time I was called, he contracted a severe cold, which was followed by a hacking cough, dyspnœa, palpitation, and precordial pain. Two weeks before I saw him, he was compelled to give up work because of vertigo and general weakness. There was no history of hæmoptysis or aphonia. I found the patient suffering from nausea, dyspnœa, a dry, hacking cough, with his face exhibiting extreme anxiety. Temperature in axilla 100.2°; respiration, 31; pulse, 112, and of typical "water-hammer" character. Urine, 58 ounces; specific gravity 1,010; no albumen or casts present.

*Physical examination.*—Cardiac dulness increased to the right of sternum a very little. Epigastric pulsation marked. Apex-beat diffused. At ensiform cartilage a double murmur was heard, which was loudest at the base. At the apex a small systolic murmur, traceable to the anterior axillary line, was audible, and the diastolic murmur of the base was strongly conducted to this point. The systolic murmur heard at the base was conducted to the arteria innominata and to the carotids, which exhibited marked pulsation.

*Left lung.*—A few moist broncho-pneumonic râles were audible at the base.

*Right lung.*—Perfectly clear.

I ordered small doses of Squibb's digitalis with the liquor ammoniæ acetatis, confined the patient to bed, and restricted his diet to liquids. He steadily improved until October 15th, when, contrary to orders, he underwent a severe exertion, after which he exposed himself and got a chill. His cough became more troublesome and he complained of more palpitation. I saw the patient on the following day, and he exhibited the same physical signs already noted, together with a double pericardial friction-murmur at mid-sternum. Heart-sounds somewhat muffled and cardiac dulness increased. Free moist râles over both lungs. Feet and legs slightly œdematous. Cough increased and incessant. Abdomen distended with flatus. Temperature, 101°; pulse, 124 and weak; respiration, 38. Patient died at eleven o'clock that night.

*Autopsy*, fifteen hours after death.—*Lungs* very œdematous, with some fluid in both pleural cavities.

*Pericardium* contained nine ounces of straw-colored serum.

*Heart.*—Some small "milk spots" on surface and phlebolites in two cardiac veins. Left ventricle hypertrophied excentrically. Left auricle slightly dilated. Other cavities were normal.

*Aorta.*—A little dilated.

*Aortic valve.*—*Left anterior segment* thin, with the sinus of Valsalva much distended. The right half of this segment exhibited a round opening the size of a crow's quill, which led into a sac that was perforated by a number of slits, which are represented in the accompanying cut. Many of the thin

shreds thus formed were attached by one end and the other floated about freely in the blood-current.

The left half of this segment was perforated by a small opening with clean-cut edges, which led directly into the ventricle. The attachment of the segment to the right anterior was much thickened by atheroma. Its other attachment was normal.

*The posterior segment* of the valve became gradually thicker as it approached the right anterior, where the upper part of the frænum was absent, and the attachments, much thickened, fell over into the ventricle.

*The right anterior segment* was perforated on its right half by a semilunar opening with clean-cut edges. One coronary artery opened behind the left anterior, and the other behind the posterior segment.

*Mitral valves.*—A large patch of irregular vegetation was found attached to the cusp immediately under the aortic valve.

*Liver.*—Congested and somewhat fatty.

*Kidneys* weighed seven and one-half ounces each, and were also congested.

New Hospitals in Paris.—A new hospital has been opened in the Quartier Latin. It contains one hundred and fifty beds. It is divided up into well-ventilated rooms, each comprising eight beds. The system of ventilation is such that air is admitted from above and below, each patient receiving seventy cubic metres. There is also a lying-in room, a histological laboratory, and a dissecting-room for one hundred and twenty students. The hospital cost 1,800,000 francs.

A. M. Valcassy has left a bequest of 1,000,000 francs to the state for the establishment of an asylum for persons injured by accidents. It will be built in the neighborhood of the Vincennes woods.—*Cor. Monthly Review of Medicine and Pharmacy.*

## ROOSEVELT HOSPITAL, NEW YORK.

SERVICE OF DR. FRANCIS DELAFIELD.

### A CASE OF EMPYEMA TREATED BY INCISION AND COUNTER-OPENING—RECOVERY.

(Reported by J. West Roosevelt, M.D., House Physician.

THE following case seems worthy of record on account of the short time in which a cure was effected.

Laurence M——, aged thirty, a native of Ireland, married, was admitted to Roosevelt Hospital on March 11, 1881. Family history good. Always in good health prior to present attack. No history of syphilis; moderate drinker.

On January 26th caught "cold in his head." Nine days later, after slight exposure to wet and cold, had a single, not severe rigor, followed by pain in the left chest, and fever. Became delirious. Recovered somewhat, but did not regain his former strength. Five weeks ago, he states, a physician drew off a few ounces of clear fluid from his left chest by means of an aspirator. Felt better for a short time, and then grew much worse. Lost appetite, flesh, and strength rapidly; sweat profusely at night; feet swelled occasionally. For last two weeks has slept badly. Has had no pain since attack first commenced. On admission, poorly nourished; weak; face rather thin and pale; tongue clean; appetite gone. Bowels regular; urine alkaline, sp. gr. 1026; no albumen. Pulse good, 150; respiration 40; temperature 103.2°. Patient had a severe chill on the afternoon of admission. Physical examination revealed, over whole left chest behind, flatness, exaggerated breathing at apex, bronchial breathing and voice between the spine and angle of the scapula, and absent breathing and voice below this point. Over left chest, in front, there was dulness from apex to about the fourth rib, and flatness below, with bronchial voice and breathing over area of dulness, and absent breathing and voice below. Heart-apex one and one-half inches outside of *right* nipple line. On March 12th, thirteen ounces of rather thin, odorless pus drawn with the aspirator. Some blood was drawn with the last few drops of the pus, and the patient complained of sharp pain in his side.

Patient was put upon quinine and tonics. He had very slight febrile disturbance. Sweat a good deal. Had occasional attacks of slight diarrhœa, which were easily controlled. On March 27th began to complain of a great deal of pain in the left chest.

April 3d.—Considerable pain in left axillary line, level of sixth rib. An œdematous swelling has appeared upon the outer and posterior aspect of the left chest, from a little above angle of scapula down for four or five inches. The swelling is not red or tender.

April 5th.—Is losing ground rapidly. Sweats profusely at night and has quite marked evening rise of temperature. Apex-beat is in right nipple-line. Coughs a good deal. Drs. W. H. Draper and Francis Delafield both agree that the pus should be evacuated.

April 6th.—By advice of Dr. Delafield, ether having been administered, I made an exploratory puncture with the aspirator in the eighth interspace, and drew off a little thin, yellow, odorless pus. Using the needle as a guide, I made an incision about two inches in length in the eighth intercostal space, about three inches behind the axillary line, down to the intercostal muscles. These were pierced by the finger in order to avoid possible injury to the intercostal vessels. A stiff probe was then introduced, and an incision made about four inches in front of the first, in the seventh space, about one inch anterior to the axillary line, the tip of the probe being pressed firmly against the chest-wall as a guide. Approximately, ninety ounces of pus evacuated. A large-sized drainage-tube introduced, passing through both openings. Chest-cavity washed out with a warm solution of boracic acid (gr. v. to ʒ j.).

Operation performed under the spray, and a large Lister dressing, consisting of wet piece, with eight layers of dry carbolized gauze, and a piece of mackintosh, applied. Pulse remained good throughout the operation. Patient rallied well. Was kept lying upon right side during the night. The temperature, which was 102° in rectum on the morning of the operation, fell that evening to 99.2°. Respiration remained about the same. Pulse was of about the same frequency and a little stronger.

The patient slept well on the night following the operation. In the morning, discharge having appeared at the edge of the Lister, it was renewed under the spray, and a small quantity of boracic acid solution was run through the tube. No attempt was made at this or any subsequent dressing to wash out the whole pleural cavity.

On April 10th a quantity of salicylated cotton was added to the dressing, being placed over the wet piece.

On April 15th, patient was allowed to sit up for the first time while the dressing was applied. As he did so seven or eight ounces of healthy-looking, odorless pus ran out through the tube. Warmed carbolic acid, one-fortieth, was now run through the tube.

After this the Lister was renewed according to indications, and nothing of note occurred until April 28th, when, there being very slight discharge, a simple dressing, consisting of wet piece covered with salicylated cotton, was applied instead of the Lister. The spray was discontinued. Patient had gained wonderfully in strength and appetite. Had no cough. Examined by Dr. Delafield, who found that the lung had expanded to the angle of the scapula.

May 4th.—Smaller drainage-tube inserted. Discharge slight in amount. Very little pus, mostly serum.

May 11th.—Tube shortened one-half, and posterior opening allowed to close. Patient has been up for some days past. Only a few drops of serum from tube. No pus.

May 22d.—Tube removed, and opening kept open for a few days longer by a tent of carbolized gauze.

June 1st.—Patient had a severe chill. Wound looks healthy. Ordered quinine. Temperature fell to normal after the chill, and remained so. During the attack it rose to 104.4°.

June 2d.—Tent removed by order of Dr. Delafield, and sinus allowed to close.

June 10th.—Sinus closed. Examination of chest by Dr. Delafield revealed in front considerable retraction left side of chest. Left shoulder lower than right. The top of sternum is drawn over to the left side. Heart in normal position. Resonance in front normal, breathing not quite so loud as on the right side.

Behind.—Some lateral curvative of spine. The

upper part of the spine is drawn to the left; the centre of the spine somewhat to the right. Flatness on percussion from angle of scapula down, and dulness from angle to top of lung. There is natural breathing from top to bottom of lung; but it is not so loud as on the right side. The voice is heard down to the bottom of the lung.

The patient has gained much in strength. Appetite good. Color returned. Feels perfectly well. Discharged cured.

On July 8th he visited the hospital in good health, having regained almost all his former strength.

In this case especial care was taken to wash out the chest as little as possible, and the details of Lister were fully carried out. No mechanical means were employed to inflate the lung, and the success of the method was most gratifying. The temperature after the operation did not rise above 100°.

## BELLEVUE HOSPITAL.

SERVICE OF DR. POLK.

(Reported by George M. Swift, M.D., late House Physician, and Charles C. Barrows, M.D., House Physician, Bellevue Hospital.)

### A CASE OF EMPYEMA TREATED BY ASPIRATION—LATER BY INCISION ANTISEPTICALLY—RECOVERY.

AT this time, when so much interest is manifested in the treatment of empyema, the following case, in which repeated aspiration was thoroughly tried and proved unsuccessful, is especially valuable.

Jacob Asacson, aged twenty-two years, a Norwegian sailor, admitted to Bellevue Hospital, February 12, 1881. Patient's previous history good. Landed in New York, January 12, 1881, feeling perfectly well; says he was taken sick January 16th. Upon questioning him as to this illness, the patient gives the rational symptoms of a pleurisy with effusion. About two weeks before admission, he says that he began to sweat at night and has lost flesh and strength since; suffers considerably with dyspnœa. Upon admission, patient is a large-boned man, apparently somewhat emaciated; dyspnœa severe; respiration, 46; pulse, 132; temperature, 100° F.

*Physical examination.*—Marked bulging of the left side of the chest, which does not move with respiration; measurement upon the level of the nipple, left side, is eighteen and a quarter inches, right side seventeen inches. Over the left chest are found all the signs of fluid in the pleural cavity, and the hypodermic needle withdraws pus. Apex of heart beneath right nipple. Sixteen ounces of pus withdrawn by aspirator, with considerable relief of the dyspnœa.

February 13th.—Twenty-six ounces of pus withdrawn in the morning, and thirty-two ounces in the afternoon. Patient was ordered the best diet the hospital affords, ale, iron, quinia, and strychnia. It was thought best to withdraw the pus by frequently repeated aspirations rather than to withdraw it all at once. This plan was pursued, and for a week the side was aspirated daily; at the end of this time the note is as follows:

February 19th.—Patient says he is better; eats well, sleeps comfortably. His left side is now somewhat retracted, and is one-half inch smaller than the opposite side. About three ounces of blood-stained pus withdrawn. Bronchial breathing and voice are heard over the greater part of the lung. Below the seventh rib are absence of respiratory murmur and voice. Heart-apex now behind sternum. The condition of the patient was in the main good, but he constantly, though gradually lost ground. His appetite was usually good, but he continued to become more emaciated. Pulse never fell below 100—and at times rose to 120. Respiration averaged 25. Temperature was below 100° F. until February 20th, when it rose to 102° F., and after this date assumed a hectic character. Usually the temperature would fall after an aspiration.

February 26th.—It was proposed to perform the Lister operation for empyema, but the patient refused his consent. Accordingly the aspirations were continued as often as every second or third day: the left side continued to retract, the measurement of March 4th showing its circumference to be fifteen inches, that of the right side sixteen and three-fourths inches. The left lung seemed to have expanded somewhat. From this time the patient became worse. The retraction of the left side was so great that it was with difficulty that the needle (a medium-sized one), of the aspirator could be introduced between the ribs. Each aspiration withdrew about twenty ounces of pus, which was never of a foul odor.

March 17th.—The note is nineteen ounces of chocolate-colored (blood-stained) pus withdrawn; patient complained of much pain during the operation; the side had become very sore from the frequent introduction of the needle. He is weak, pale, and anæmic.

March 24th.—The patient, having given his consent, was etherized, and an incision was made into the left pleural cavity, in the sixth intercostal space, in the axillary line, under the carbolized spray. The intercostal space was too narrow to admit the introduction of a drainage-tube, and accordingly was enlarged by nipping off with bone-forceps enough of the upper edge of the seventh rib to admit it. Two hard-rubber tubes, fastened side by side to one another, were introduced, and a large pad of borated cotton placed over their external openings. The amount of pus and blood that escaped during the operation was considerable, but could not be measured. The Lister dressing was applied over the borated cotton, and a rubber bandage snugly over the whole chest. The patient was much exhausted after the operation. The dressings were changed in the evening of the same day under the spray, there having been a free discharge of pus through the tubes. In the course of a day or two the patient was in better condition, but complained of great pain in his side. This was thought to be due to the pressure on the ribs by the hard-rubber tubes, and was relieved by partly withdrawing them. The dressings were changed twice daily, and always under a carbolized spray.—G. M. S. (Dr. Swift's service in the hospital terminated April 1st, and the case came under the care of Dr. Barrows.)

From April 1st to April 6th the side was dressed daily under the carbolized spray. The hard-rubber tubes being so large as to cause pain by their pressure, they were replaced by two pieces of flexible English (Weiss) catheter, No. 10, secured to each other side by side, and held in position by carbolized silk thread, strapped to the chest with rubber plaster. The dressings were reapplied as described above. The note of April 6th is to the effect that the daily discharge has decreased, and now amounts to about two ounces of thick, yellow pus, not offensive in odor. This pus drains directly into the borated cotton.

On April 7th the tubes were removed, when about six ounces of greenish yellow pus escaped from the opening. They were then cut shorter and reinserted, the patient having complained that they were "sticking into him." The patient was then more comfortable. On April 8th the patient sat up for the first time. Discharge is very small in amount, and less green in color.

April 12th.—Patient continues to improve. Eats well, sleeps soundly, and suffers no pain. The daily discharge since the last note has been small in amount, and not offensive in odor. To-day six ounces of yellow pus, with no bad odor, came from patient's side during the dressing.

April 13th.—An ounce and a half of pus came away.

April 14th.—One drachm of pus discharged.

April 15th.—The drainage-tubes became displaced yesterday, and this morning the discharge from the side amounted to about two ounces. A piece of solid tissue, dark and shreddy, and not offensive, as large as a man's little finger, and resembling a piece of old fibrous adhesion, came from the opening.

April 17th.—As there has been some difficulty in retaining the double tubes in position, a single tube of the same material is substituted for them.

April 23d.—Since the last note the daily discharge continued to decrease in quantity till the 22d, when the dressings were scarcely stained. On the evening of the 22d the temperature rose to 100¼° F., it having been below 100° F. previous to this since the operation, and this morning the patient complains of pain in his left side and shoulder. The single tube is removed, and a soft rubber drainage-tube about three inches long (with fenestra) is introduced well into the pleural cavity, and about four ounces of pus are discharged. The tube is left in, and the dressings are reapplied.

April 29th.—Discharge is growing thinner and more scanty every day.

May 4th.—The cavity is syringed out with two per cent. carbolic solution to-day for the first time.

May 13th.—Dressings are now changed every two days. The cavity was filled with carbolized water, and found to be about three ounces in capacity.

May 23d.—A carbolized oakum tent is to-day substituted for the drainage-tube. The physical signs seem to indicate that the lung is expanding.

May 26th.—While the tubes remained in the incision the patient frequently complained of pain along the course of the intercostal nerve of the space in which the incision was situated, and which was believed to be due to pressure on the nerve. This has ceased since the tent has been substituted for the tubes.

May 31st.—Discharge very scanty. Cavity, when injected again to-day, is found to be much smaller in size than when last injected.

The patient has no pain, and says that he feels well. He is gaining flesh and strength daily. The apex-beat of the heart is now in its normal position. Over the lower two-thirds of the left side posteriorly are found, on physical examination, diminished vocal fremitus, bronchial voice, and distant, faint, bronchovesicular breathing.

June 2d.—Tent removed; dressings reapplied.

June 6th.—Dressings removed; no discharge; reapplied.

June 9th.—Sinus has closed.

June 14th.—The wound of the incision has healed, and no further dressing is necessary.

July 10th.—Since the last note the patient has been apparently entirely well, and, besides taking care of the house physician's rooms, has been doing a large share of the heavy work about the ward. He is anxious to go to sea again, and is only kept in the hospital until he can procure a position upon some suitable vessel. Physical examination indicates that there has been no reaccumulation of fluid, and in order to prove this the exploring (hypodermic) needle has been several times introduced, and has each time failed to bring away any fluid. Physical examination to-day shows slightly diminished motion of the left side. The left side measures on the line of the nipple sixteen inches (one inch more than when the operation was performed), and the right side seventeen inches at the same level. Over the upper two-thirds of the left side the vocal fremitus, percussion-note, vocal resonance, and respiratory murmur are normal, while over the lower third there is dulness, diminished fremitus, vocal resonance, and respiratory murmur, as over a thickened pleura.

From February 12th, when the patient came into the hospital, until March 24th, when the side was opened, aspiration was performed nineteen times, the total amount of pus withdrawn being three hundred and ninety-five ounces; the smallest quantity withdrawn at any one aspiration being one ounce, and the largest, thirty-two ounces.

The last two aspirations were performed on March 19th and 22d, and resulted in the withdrawal of thirty-two and twenty ounces of pus respectively. It is thus seen that the production of pus was not at all diminished by the frequent aspirations. At no time during the whole course of the treatment after the operation were the dressings removed, except under the carbolized spray, and with full antiseptic precautions, and it is believed that to this the successful result is mainly due. The borated cotton makes an excellent addition to the Lister dressing in such cases, as the discharges, which are apt at first to be profuse, are readily absorbed by the cotton, and do not so quickly soak through the dressings. The rubber bandage which was applied over the whole chest, from the armpits to the waist, served to hold the dressings well in place, to make a firm and gentle pressure on the chest-walls, and to prevent the entrance of air beneath the edges of the dressings; and it is believed that this contributed not a little to the success of the case.

---

URETHROSCOPY AT VIENNA.—By no means the least important of recent Vienna promulgations are the researches of Dr. Jos. Gruenfeld with the endoscope, or rather urethroscope. Beginning in 1871, as assistant in Sigmund's extensive syphilis division of the Vienna General Hospital, he has steadily and perseveringly pursued his studies with this instrument, and has finally earned deserved attention and recognition, not simply for himself and his method, but also for the subject—*urethroscopy*. This recognition took tangible shape in the form of an invitation by Billroth to write a volume for the "System of German Surgery," edited by Billroth and Luecke, of Strassburg, now appearing. The book appeared last year is being already translated into Italian, and will soon appear in English. That the author has somewhat exalted notions as to the future of endoscopy is not unnatural; but that he gives valuable information as to the investigation and treatment of pathological conditions in that small but troublesome field, the urethra, is acknowledged even by his fiercest opponents and critics.—*Cor. Chicago Med. Journal and Examiner.*

# Progress of Medical Science.

SUCCESSFUL REMOVAL OF A CALCULUS BY RAPID DILATATION OF THE URETHRA IN A FEMALE CHILD.—Mr. R. W. Parker reports (*Medical Press and Gazette*, May 14, 1881) an interesting case of calculus vesicæ occurring in a female, aged five years, and its successful removal by rapid dilatation. The bladder-symptoms seemed to have commenced two years ago, at which time the patient experienced difficulty in passing her water when in the upright position, never voiding any urine at night in the recumbent posture. On passing a sound into the bladder, a calculus was at once detected. The urethra was dilated with a three-pronged dilator until the little finger could be introduced. The stone was then seized and removed piecemeal. On examining the fragments, a nucleus was discovered, which was found to be composed of uric acid. Five days after the operation the patient was able to retain her urine during the lay. In three weeks she was discharged cured.

ON THE DIAGNOSIS OF CARIES OF THE SPINE IN THE STAGE PRECEDING ANGULAR CURVATURE.—In the *British Medical Journal*, June 11, 1881, Mr. Howard Marsh mentions the following order of symptoms as an aid to diagnosis: First, pain, which varies widely in different cases, both as regards its quality and in the degree of its severity. In disease involving the first two cervical vertebræ it is referred to the occipital region of the scalp. In other regions of the spine, pain, when it is present, is felt either at the affected part itself or below it. It is very rarely, indeed, situated at a higher level. If a patient complain of pain above the suspected spot, the presumption is either that it depends on caries at some point higher up, or that it is not due to caries at all, but to some other cause. Pain attending caries in the lower cervical region radiates over the shoulders and down one or both arms, and sometimes also over the front of the upper part of the thorax. When the dorsal spine is affected, pain is felt around the sides of the thorax—sometimes on one side only, sometimes on both—or at the middle line in front. When the lumbar spine is involved, pain spreads over the loins and pelvis and down the lower limbs—sometimes as far as the knee, sometimes even to the feet. The true meaning of pain in these various situations is apt to escape notice. Thus, in a patient with disease of the lumbar spine, pain, passing through the hip to the back of the thigh, had been attributed to sciatica, no doubt with the less hesitation because it was limited to one side. In other instances, again, pain complained of in one knee, and accompanied by an altered gait, has led to the belief that the patients had hip-disease. The uneasiness of pain caused by driving or railway travelling is often very suggestive. Some patients who can walk slowly and cautiously without pain, suffer severely from the jarring of a vehicle. The explanation of the fact probably is, that in the effort of walking the surrounding muscles brace up and steady the spine, while in the sitting posture they are more relaxed. Coughing or sneezing, or a false step, may occasion pain in the region of the spine affected.

The second order of symptoms by which caries of the spine in its incipient stage may be recognized, refers to the degree in which the column retains its natural mobility. These symptoms must be brought out by various exercises which the patient is made to perform. The test of picking up some small object, difficult to seize, such as a coin or a pencil, is a very telling one, especially in the case of children. If the spine be sound, the patient will stoop and raise himself without a pause, without hesitation, and without restraint; but, if mischief be present, his proceedings are often very characteristic. A glance will show that he is calculating how to manage so that he can keep his spine at rest. If the disease be acute, he will probably give up the attempt, and say that he cannot stoop. If he persevere, he will probably place himself so that the object is at his side; he will then cautiously bring his hand toward the ground, not by bending or inclining the spine, but by flexing his knees, while his spine is kept rigid and nearly perpendicular. Having at length succeeded in grasping the object, he will pause so as to be sure of his balance, and will then raise himself by straightening the knees, while, as before, he keeps his spine rigid and upright. In children, the suspicion that caries is present is strongly confirmed by the observation that the patient has some device for relieving the spine of part of the work of supporting the weight of the head and trunk. Thus, in disease of the cervical spine, the patient may be seen to rest the chin on the hand, or to support the head with the hands, especially in the effort of rising from the recumbent posture. Some children with cervical caries will sit for hours with their elbows on the table, and with the hands supporting the head. Others, who have disease in the dorsal or the lumbar region, have the habit of making their way to a chair, on which they place the palms of their hands, and over which, with their arms straight, they lean, so as to give themselves "high-shoulders," and so that weight is taken off the spine and transmitted through the arms. Another posture, very suggestive of mischief, is that in which the patient, having slightly flexed one knee so that the limb rests on the toe, places the hand on the middle of the thigh, and then leans over to that side, so as to convey weight from the shoulder through the arm, and so to the thigh. These schemes for the "collateral transmission of weight" are always worthy of very careful attention. Tapping with the knuckles on the spinous processes of the suspected vertebræ, Mr. Marsh regards as entirely untrustworthy. Another symptom, on which some observers lay much stress, is tenderness or increased sensitiveness found over the spinous processes corresponding to the carious vertebræ. It is a very common feature in cases of hysterical spine, and certainly tenderness is often absent when caries is distinctly in progress. The period at which angular curvature becomes apparent in the course of spinal disease varies with the form that the caries assumes. In instances in which inflammation involves the general substance of the body of one or more of the vertebræ, and is attended with rapid softening and absorption, angular curvature very soon results; but in some cases inflammation is limited to the external surface of the bodies of the vertebræ and their investing ligaments. Here extensive ulceration may take place, and even lead to the formation of a large abscess, before angular curvature ensues. Several examples have lately been seen in which iliac abscess, due to caries of the vertebræ, was present before angular curvature was perceptible, although it was developed at a later stage.

GLOMERULO-NEPHRITIS.—Dr. D. J. Leech has reported three cases in the *British Medical Journal*, June 25, 1881, which seem to indicate that glomerular changes may play a most important part in the production of the clinical phenomena in Bright's disease. The cases recorded presented very similar clinical symptoms. They ran a course of from two to six months. In all, general œdema was a conspicuous symptom, and the urine, small in quantity and of low specific gravity, contained a large amount of albumen. In none of them was the heart considerably hypertrophied. Pathologically, too, they resembled one another in this, that the glomerular changes seemed to depend on cell-accumulation between the glomerulus and the capsule, which assumed to a greater or less extent a fibroid appearance, and eventually led to destruction of its function. The changes resemble those which are met with in scarlatinal nephritis. Dr. Leech inclines to the opinion that the fibroid appearance mentioned is due to the flattened condition of the proliferated epithelial cells, arising partly from natural mode of growth, partly from pressure; and that this change may take place both in the epithelial cells from the glomerular surface, and in that of the capsular surface. He doubts that the cell-elements are derived from the interstitial tissue contained in the glomerulus. Firstly, because the appearance of the cell-growth between the glomerulus and the capsule appears to betoken an epithelial origin; secondly, because it appears not yet proved that interstitial tissue exists in the glomerulus. There was a very marked distinction in the appearance of the glomeruli in the cases reported. In the first, the changes seemed largely connected with the capsular epithelium, though there were in many parts indications that the glomerular epithelium was also affected. In the second and third cases, whilst the capsule was thickened and its epithelium considerably changed, the cell-accumulation seemed connected for the most part rather with the epithelium covering the glomeruli than with that over the capsules. With regard to the effect of changes in the capsule and its epithelium, and in the glomerulus and its epithelium, it is evident that we may possibly have different results, if, as seems probable, these changes can occur separately, or if one can greatly predominate over the other. Of course, in later stages, when the surfaces of the glomerules and capsules are united, the function of the former is abolished; but, in an earlier stage, effects of capsular stages may possibly differ from those of glomerular epithelial changes, and eventually be recognized clinically.

PHLEGMONOUS INFLAMMATION OF THE MAXILLARY, FRONTAL, AND SPHENOIDAL SINUSES OF THE ETHMOIDAL CELLS. — Weichselbaum reports three cases of this affection, no mention of which is made in the current text-books. The course of the disease was uniformly and rapidly fatal. The first patient was a robust soldier of twenty-one years, who had always been previously healthy, and was admitted into the Viennese military hospital on February 5th of the present year, with "*tetanie*." The symptoms of the latter gradually abated until March 8th, when a marked deterioration of the patient's condition suddenly set in, with elevation of temperature, symptoms of meningitis, and moderate icterus. On March 10th, an erysipelatous patch of the size of the palm was noticed on the right cheek, but did not extend, and on the following day the patient died. In the second case the course of the disease was still more rapid. A previously healthy soldier complained, on the morning of April 26th, of malaise and headache, but was able to be about. On the next day he complained of pain in the brow and upper jaw, there being, however, no objective signs except a febrile condition. Toward evening the condition became suddenly worse, the lips being cyanosed, with stertorous breathing, convulsions, and trismus, and death occurred during the night. The third patient was a woman of sixty-four years of age, who, after feeling unwell for several days, was attacked on April 26th with a chill, followed shortly after by erysipelas, commencing on the nose and extending to the cheeks and scalp. The patient died on May 1st.

In all of these cases a very peculiar condition was found post-mortem in the antra, frontal sinuses, and sphenoidal and ethmoidal cells. These cavities, especially the antra, were filled with a purulent fluid, while the lining involucrum was permeated with numerous opaque, yellowish white, partly disseminated and partly confluent patches of the size of a millet-seed and upward, the largest having a length and breadth of one to two ctm. and a thickness of three to five mm. These patches consisted of fibrinous exudation in process of purulent liquefaction, situated in the substance of the mucous membrane and periosteum, and were partly covered by the superficial layers of the macerated and yellow mucous membrane, while the larger plaques were exposed to view by ulceration of the latter. The mucous membrane between the patches was uniformly swollen, and was in part intensely congested, in part the seat of extravasations of blood. Besides these changes, there were present, in the first case, acute pachymeningitis in the anterior cerebral fossa, with purulent leptomeningitis, extravasations into the tissue of the pleura and pericardium, cloudy swelling of the liver, etc. In the second case (in which the disease had lasted only two days) the spleen was slightly enlarged, and the liver was in a condition of granular and fatty degeneration. Pachy- and leptomeningitis were also found in the third case, with consolidation of the anterior lobe of the left lung, enlargement of the spleen, and fatty degeneration of the heart, liver, and kidneys. As regards the nasal cavities, they were in all three instances but slightly altered. The mucous membrane was moderately congested and showed a few ecchymoses. Microscopically, the above plaques consisted of a dense reticulum of delicate threads of fibrin, in the interstices of which more or less pus-cells were scattered, the superficial layer of the mucous membrane being, as a rule, not infiltrated. The author considers the affection to be, anatomically, a croupous inflammation of what may be regarded as the equivalent of the submucous tissue of other mucous membranes, the only difference being that in these cases the exudation was mainly fibrinous, while in other situations it is more purulent. The affection is to be regarded as a primary infectious disease, ending fatally in the first and third patients by extension to the meninges, while in the second case death was due to a general systemic infection.—*Allgem. med. Centralzeitung*, June 22, 1881.

THE AMERICAN GYNECOLOGICAL SOCIETY.—One of the events of the week has been the annual meeting of the American Gynecological Society in this city. The meeting has proved a success in every way. At a future time we shall present our readers with the usual report of its proceedings.

# THE MEDICAL RECORD:

## A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, September 24, 1881.

## THE END AT LAST.

The shock of President Garfield's death has been felt by none more keenly than by the medical profession. As a body the physicians of this country have watched the varying course of the symptoms with more intelligence and with no less sympathy than the rest of their countrymen. Perhaps a special knowledge of the case gave to the profession earlier assurance that the end must be a fatal and sorrowful one; but the blow struck just as sharply for all that.

This is not the place for eulogies of the dead, or for expressions of the sorrow and sympathy with which the land has been filled. We would, however, even though it be unnecessary, urge one thing with force upon our readers: the best tribute which the medical profession can pay, alike to the memory of our late President and the dignity of the art we practise, will be to avoid all carping criticism on the methods of the medical attendants; to let no scandal arise because of private grievance; to use the broad charity which is so well deserved by those who have worked with untiring faithfulness for the life they have had in charge. It is, we believe, the general verdict of the profession that the late President received all the aid which medical science, intelligently applied, could furnish. Looking back upon the case, even with the light of the autopsy before us, it is impossible for any one to say that any different mode of treatment would have saved the patient's life. And furthermore, we may claim that medical art prolonged for months a life which might otherwise have ended in a few days or weeks. We believe that this can be truthfully said, and that it will be echoed and endorsed by the medical profession.

After our notes, made in the last issue, upon the President's case, there was no material change in the symptoms until Friday, the 16th. There was then an increase in all the febrile symptoms. The pulse became weaker and more fluctuating, the respiration was more rapid, and the cough more annoying. There were evidences of a lobular pneumonia. There was an increase in the fever also. The secretion of pus from the wound and the parotid abscess was less in amount. The medical attendants officially acknowledged the existence of septicæmia. During the night the pulse fluctuated from 116 to 130, the temperature remaining normal.

Saturday morning the pulse was 108, respiration 21, temperature 99.8°. At 11 o'clock, the patient had a severe chill lasting half an hour, accompanied by vomiting and some mental disturbance. It was followed by profuse perspiration. During most of the remainder of the day the President slept, taking nourishment and stimulants at intervals.

On Sunday the 18th, there was a slight fever in the morning; in other respects the symptoms were not specially alarming until 6 o'clock, when another chill lasting fifteen minutes came on. Profuse sweating followed; also a fever which lasted until midnight. The pulse varied between 112 and 130. During the day liquid food and stimulants were given. Hot applications were also frequently made to prevent threatened rigors and to keep up the temperature, which showed a tendency to fall below the normal.

On Monday, the 18th, at 8.30 A.M., a third chill came on, lasting about fifteen minutes, and presenting similar characteristics to those which preceded it. At 6 P.M. a bulletin was issued stating that the pulse was 102, respiration 18, and the temperature 98.4°. There had been no especial change during the day. At 10.10 P.M. the patient awoke from a sleep, complaining of severe pain over the region of the heart. He almost immediately became unconscious, and died half an hour later.

As will be seen from the autopsy, the official account of which appears in another place, the immediate cause of death was internal hemorrhage. Although such an occurrence was not deemed impossible, the particular way in which it took place had not been anticipated by any of the surgeons in attendance. In fact, in attempting to reconcile the diagnosis of the case with the necropsical revelations, we are met with surprises in several directions. Notwithstanding the great amount of careful and intelligent study of the case, the precise course of the ball was not made out previous to death. Considering the parts involved, the strange deflection of the missile, and the extent of its penetration, any satisfactory and safe exploration would have been impossible. Indeed, the opening through the body of the first lumbar vertebra appears to have been discovered accidentally, as was also the ball itself. The missile was really found in the mass of intestines and annexa after removal of the latter from the body. The supposed track of the ball proved to be nothing but a burrowing sinus connected with the fractured

eleventh rib. The large pus-pouch under the liver was evidently due to the same condition, becoming converted into a closed sac by unequal healing of the course of the sinus. There was a remarkable absence of metastatic abscesses, notwithstanding the case was clearly one of chronic septic infection. We learn that, with the exception of a small pus-pellet in the left kidney, none of the vital organs were involved; and this in the face of the fact that during the last days of the patient's life there was an ominous development of pulmonary trouble.

In reviewing the case from an autopsical standpoint, it is quite easy to offer criticism. The stubborn facts of a post-mortem always stand out in bold relief against decisions rendered ante-mortem. But it must be recollected that there were peculiar difficulties in the case. They are best appreciated by all who have had experience in the treatment of gunshot wounds. However greatly we may regret that, in view of the great public importance of the case, a correct opinion as to the course of the ball was not made at the beginning and was not proven at the end, it is quite difficult to see how the error could have been avoided. There were no symptoms during life to point to the locality of the ball. But, even at the worst, as proving that the surgeons never knew during the life of the patient where the ball was located, there is nothing to show that in consequence of that error the patient suffered. The ball itself, by being firmly encysted, became harmless, while the real cause of all the trouble had its origin seemingly in the comminution of the eleventh rib. It is a matter for much congratulation that the bullet was not found in a pus-cavity. Under such circumstances, even if it were impossible to remove the bullet, there would have been many who would have claimed that such an operation should have been attempted, or at least that the neglect to resort to such a procedure was indirectly the cause of the patient's death. But all doubts in such a direction are cleared up by the autopsy. On the supposition that the ball should have been extracted in any event, what have we not escaped? At least the wisdom of not cutting down upon the missile until the locality of the latter was clearly made out, cannot be gainsaid. As nearly two hours were consumed in finding the ball at the autopsy, what might have been the chances of extracting the missile during life?

In commenting thus in a general way upon this remarkable case, we have to say that its strictly medical history is not yet complete. It was our intention in the present number to have given to the profession a full report, with illustrations, from Dr. D. W. Bliss, the attending physician to the President. For obvious reasons Dr. Bliss has been prevented from preparing his account of the case in time for use in this issue. We hope to be able to present it in our next, with the necessary diagrams of charts and carefully made illustrations of pathological appearances. As this report will be made exclusively to the RECORD, we shall spare no pains to make it acceptable to our readers.

---

### WORRY AND BRAIN-EXHAUSTION.

IN a leading English periodical, Dr. Mortimer Granville has been discussing a subject which should particularly interest the impetuous workers on this side of the water. Referring to the increasing number of cases of sudden collapse from alleged "overwork," Dr. Granville offers some views which, if not exactly new, are at least not those currently entertained.

Constant warnings are being given at the present time against over-work. But, thinks the author quoted, these are generally misapplied. The brain can be tired by prolonged activity, just as may happen with a muscle. But we find that hard and persistent muscular work does not cause muscular collapse. Each day the reserve forces of nutrition renew the wasted protoplasm, and the frame keeps as strong as ever. So there is no more reason why there should be brain-collapse from systematic, though severe brain-work, than there is for paralysis or tetanus to strike down athletes or day-laborers. And we do, indeed, find that brain-workers are, as a rule, long-lived.

The cause of the frequent breaking-down of men engaged in the active work of life is referred, therefore, by Dr. Granville, to another source, and that is worry. Doubtless it is no new thing to be told that it is not work, but worry, which kills. But it is often useful to have general impressions fixed upon a definite and more or less scientific basis. Therefore we follow our author in the expansion of his views.

It may be assumed that, as the contraction of a muscle is caused by successive waves of nerve-impulses, so the mental activities are made up, after an analogous fashion, of undulations of nerve-impulses. In ordinary work, however hard, these impulses are sent out in a regular and rhythmical manner. It is the worry which comes in and disturbs this rhythm, exhausts the nerve-force, exhausts further the reserve or recuperative power, and breaks down the man. The strength does not weary of digesting digestible food; but add an unmasticated bolus of tough beef-steak three times a day, and there will be trouble eventually. Worry produces a kind of dyspepsia of the mind. It is to the encephalon what restaurant-pie is to the stomach.

The first inference from this presentation of the matter is easy and natural. It is that we should not worry. Such advice is perhaps the most fruitless that can be possibly given. Nevertheless, a diligent inculcation of it, and especially its application in educating the young, may not be without some avail.

If a man knows that he can hardly overwork himself (taking Dr. Granville's view), provided he preserves a philosophic calm, the knowledge can but be a help.

A second inference drawn, is that the fear of overwork need not be made the excuse for idleness. This caution applies especially well to the bringing up of children. Many parents are no doubt too anxious lest the minds of their growing offspring be overtaxed. There is danger for children in confinement and close study; but the greater danger and the break-downs come when to the study is added the anxieties and worry of examinations, competitions for prizes, and the other paraphernalia for the artificial excitement of children to extra and spasmodic industry.

### DRIFTING TOGETHER.

Our esteemed contemporary, the *Lancet*, lately published two editorials which brought out a confession from the homœopathic fraternity that deserves some comment.

Discussing the venerable subject, *similia similibus curantur*, the editorial writer showed, with great clearness, the fallacy that lies in the foregoing aphorism, even granting the facts alleged to support it. Thus the homœopath finds that aconite, given in full doses, produces a condition resembling somewhat that of inflammation. Therefore, he gives aconite in small doses to cure inflammation. But the action of this, as of other drugs, is entirely different in small and large doses. And in the doses used for the treatment of inflammation it would, if given to the healthy or diseased, produce no inflammatory symptoms. The action is really, as nearly as words can express it, *antipathic*, not homœopathic.

Again, large doses of ipecac produce vomiting, small doses sometimes prevent it. But the action is not homœopathic, for small doses of ipecac are soothing or gently tonic. So with jaborandi: the small doses which sometimes relieve night-sweats are not the doses which would ever cause diaphoresis, but are those which give tone to the centres that larger doses paralyze. In the same way we might go through the list of drugs so often held up as illustrating the marvellousness of the homœopathic law: caffein for insomnia, podophyllin for diarrhœa, rhus toxicodendron for eczema, cantharides for vesical irritation. Such facts only show that tissues are differently affected according to their nutritive condition, or the amount of the drug that reaches them. To a certain extent there is, in a good many cases, a kind of physiological antagonism between the action of the small and the large doses.

At any rate, the term "homœopathic" is manifestly a misnomer, and it cannot be legitimately applied to any class of remedies.

The above exposition is by no means a new one; but it has an interest now since it brought out an admission of its truth from a number of prominent homœopaths.

Of course, it was claimed that the name could still be used if applied to the *selection* of drugs; but that is a minor question, and one that is quite distinct from that of their therapeutical action. The fact that what is offered to the public as homœopathic treatment is not homœopathic treatment remains.

Furthermore, as regards this selection of drugs on a homœopathic principle, it can certainly not be claimed that such method of selection is always best or is of universal value. Nor can it be asserted that it is sufficient without some practical experience to corroborate the theoretical deduction.

As the better class of homœopaths have now renounced infinitesimals, and as many have admitted the fallacy implied by the term homœopathy, there seems no reason why they should not give up their dogmas altogether and drift back as fast as possible to rational medicine.

On the other side, there has also been shown a disposition to give way. At the recent meeting of the British Medical Association the most important address, that delivered by Dr. Bristowe, was upon the subject of homœopathy, and that eminent physician advocated most strongly the breaking down of all barriers and the consulting with qualified homœopaths. When such an appeal can be made and listened to in conservative England, we may well believe that there is a drifting together.

---

### THE AMERICAN ACADEMY OF MEDICINE.

The sixth annual meeting of the American Academy of Medicine was held in this city on Tuesday afternoon at the College of Physicians and Surgeons, Dr. Edward T. Caswell, of Providence, R. I., presiding, and Dr. Richard J. Dunglison, of Philadelphia, acting as secretary. The attendance was reasonably good, and much interest was manifested in the proceedings. Dr. Charles Carroll Bombaugh, of Baltimore, read a paper on "The Prevalent Misuse of the Term Allopathy." A committee of two, Drs. Dunglison and Marcy, presented an exhaustive paper on "The Condition of Legislation in Regard to the Practice of Medicine throughout the United States and the Dominion of Canada," the paper being read by Dr. Dunglison. Officers were elected for the ensuing year, as follows: President, Dr. Traill Green; Vice-Presidents, Drs. Elsberg, Strawbridge, Bombaugh, and C. C. Lee; Secretary and Treasurer, Dr. Dunglison, with a Council of thirteen members. In the evening Dr. Caswell delivered an instructive and interesting address, to which we hope to refer at another time. We are glad to learn that the association is prospering.

# Reviews and Notices of Books.

COULSON ON THE DISEASES OF THE BLADDER AND PROSTATE GLAND. Sixth Edition, revised. By WALTER J. COULSON, F.R.C.S. 8vo, pp. 381. New York: W. Wood & Co. Wood's Library of Standard Medical Authors.

THIS, the July volume, which is one of the Wood's Library for 1881, is the sixth edition of a work which has been out of print for a number of years. Mr. Coulson has revised it up to date, and given the profession one of the most valuable and comprehensive treatises on diseases of the bladder and prostate that has ever been published. The whole ground is gone over so thoroughly as to leave nothing to be desired by the practitioner who may wish to use it as a work of reference or as a guide to practice. All the latest advances in the treatment of bladder diseases are duly noticed, and an especial feature of value is a full chapter on Bigelow's method of litholapaxy.

ON CANCER, ITS ALLIES, AND OTHER TUMORS, WITH SPECIAL REFERENCE TO THEIR MEDICAL AND SURGICAL TREATMENT. By F. ALBERT PURCELL, M.D., M.R.C.S., Surgeon to the Cancer Hospital, Brompton. 8vo, pp. 295. Philadelphia: Presley Blakiston. 1881.

THIS is an attractive book in many ways. It is elegantly printed, beautifully illustrated, pleasantly written, and its subject is always full of interest. The author has had a large experience in the care of cancer cases, and he is supposed to speak with authority on the clinical points connected with the new-growths of which he treats. Although the reader is told that he must not expect anything original, either in theory as to the cause of cancer, or anything new in its treatment, he is fain to suppose that the author may be a trifle modest, and in so far give an extra interest to his work. But concerning the subject-matter he is destined to be disappointed, and is made to wonder why the author considered it necessary to write such a work. We speak of it now solely from the standpoint of originality. By itself it has much to recommend it regarding the value of its contents for the general learner. To the latter the author has done a real service in simplifying many abstruse points and in throwing much light on dark places. His general description of cancer, sarcoma, and allied growths is admirably clear, and their distinctive anatomical growths are well presented. The microscopical illustrations are particularly excellent, and serve to distinguish in a striking manner the differences in the anatomical characters of the abnormal growths, notably between cancer and the sarcomata. The study of the microscopical relations of these neoplasms is to our mind worth the price of the volume, as setting forth in a perspicuous manner the practical distinctions between the two great classes of malignant tumors. As a summing up of extensive experience, the conclusions of the author have more than the ordinary value, and will make an important addition to the clinical study of these diseases in their varied forms. The hereditary predisposition to malignant tumors is acknowledged and the local origin of the disease admitted. In order to reconcile the opposing views in regard to the relations of the two, our author contents himself with the assumption that cancer and other malignant growths are always local in origin; but there is a constitutional tendency for the development of the neoplasms born with the individuals—a want of co-ordination in cell-development, which allows of a heterologous formation in one or more parts of the body. At best this is an old idea revamped in a possibly more intelligible shape than we usually find it. As the author starts out with the assertion that no new system of treatment is to be advocated, the reader is prepared to learn that no specific for cancer has been found, not even in Chian turpentine, and that the early removal of the growth by caustics, the ecraseur, or knife, is the course which offers the best outlook for the patient. In constitutional treatment ferruginous tonics are recommended in the hope of bringing the system up to the point of resisting the inroads of the disease, and of possibly inviting a tendency to a possible atrophy of the growth itself. As a whole, the work is an important addition to the clinical history of the disease, and gives a comprehensive view of a very extensively cultivated field of observation and inquiry.

GENERAL MEDICAL CHEMISTRY, FOR THE USE OF PRACTITIONERS OF MEDICINE. By R. A. WITTHAUS, A.M., M.D., Professor of Chemistry and Toxicology in the Medical Department of the University of Vermont, Professor of Physiological Chemistry in the Medical Department of the University of the City of New York, etc. 8vo, pp. 428. New York: W. Wood & Co. 1881.

THE work before us is the August volume of Wood's Medical Library. It has been written specially for the series, by a gentleman who is an acknowledged authority and a successful teacher in his department. His aim has been to adapt the work to the wants of the general practitioner; in other words, to treat his subject more particularly as to its bearings upon physiology, hygiene, therapeutics, and toxicology. In so far he has succeeded even better than might have been anticipated, considering the acknowledged dryness of the subject and the necessity of accuracy of chemical detail. Although it is not a work which any practitioner would peruse for simple recreation, it is one which will serve its purpose as a practical guide in medical chemistry—as a volume for ready reference for the large number of medical men who, alas! are so much in need of the information which it gives. The classification adopted by the author is comparatively simple and practical. The modern system of notation has been followed, the weights and measures are given in the metric system, and the temperature in degrees of the centigrade scale.

THE MICROSCOPE AND ITS REVELATIONS. By WILLIAM B. CARPENTER, C.B., M.D., LL.D. Sixth Edition. 12mo, pp. 857. Philadelphia: Presley Blakiston. 1881.

THE sixth edition of this deservedly popular work comes to us with twenty-six elegantly finished chromo-lithographs and five hundred beautiful wood engravings of microscopical apparatus and microscopical preparations of the lower animals and vegetable kingdom. The general plan of the work is, of course, preserved in giving to the amateur microscopist all the necessary information to enable him to examine with satisfaction and profit the thousands of beautiful specimens of lower organisms which he is most likely to meet with. It is the most complete work of its kind in any language.

DANGERS TO HEALTH: A PICTORIAL GUIDE TO DOMESTIC SANITARY DEFECTS. By T. PRIDGIN TEALE, M.A., Surgeon to the General Infirmary at Leeds. Third Edition. 8vo, pp. 161. London: J. & A. Churchill. 1881.

THIS little work, as its title indicates, is intended as a guide to the ordinary householder in his attempts to find the sources of sanitary defects suspected on his premises. As such it serves an excellent purpose. By means of striking diagrams of faulty sewerage, taken from actual cases either under the observation of the author or his friends, he strives, very successfully, we think, to impress the people with the idea of general rascality in the plumber and unqualified perfidiousness in the cheap builder. The plates, seventy in number, are capitally executed, and will serve their purpose of giving at a glance some of the more glaring defects in sanitary engineering. The book should be in the hands of every householder.

ANTISEPTIC SURGERY: THE PRINCIPLES, MODES OF APPLICATION, AND RESULTS OF THE LISTER DRESSING. By DR. JUST. LUCAS, Championnière Surgeon to the Hôpital Tenon, etc. Translated from the second French edition and edited by Frederick Henry Gerrish, A.M., M.D., Surgeon to the Maine General Hospital, etc. Portland: Loring, Short & Harmon.

THE author's work has been well known to the readers of French medical literature, and has with justice been considered one of the ablest expositions of the Lister method that has been written. There is no middle ground taken regarding the value of the so-called antiseptic principle. To such as are prejudiced for or against the system, or to the much larger number who have no settled convictions, the work will prove a valuable and practical one. Every detail of the subject is worked up with the greatest care and thoroughness, and the necessity of each step is duly presented. It matters not whether the reader is a believer in the antiseptic system or not, he will find in this little work a number of valuable suggestions regarding the treatment of wounds, which he will hasten to turn to practical account. Although we will not say that no surgeon can afford to be without it, we can safely assert that every one engaged in surgical practice will add to his available stock of information by a careful study of its contents. Prof. Gerrish has made an excellent translation of the original into classical English, and infused into the whole a graceful style which affords enjoyable reading.

A TEXT-BOOK OF PRACTICAL HISTOLOGY, WITH OUTLINE PLATES. By WILLIAM STERLING, M.D., Sc.D., F.R.S.E., Regius Professor of the Institutes of Medicine in the University of Aberdeen. With thirty outline plates, one colored plate, and twenty-seven wood engravings. Philadelphia: J. B. Lippincott & Co., 1881.

DR. STERLING has added another to the already copious list of text-books on this fundamental branch of anatomy. It is certainly pleasing to note the attention now given to histology by English writers. Following as it does an era of apparent neglect, this cannot fail to stimulate the study of a very necessary department of anatomy. The present volume is handsomely made up in quarto size. Its only new feature consists in the insertion of outline plates of microscopical sections, which are intended to be filled in by the student. Doubtless, so far as histological drawings are concerned, this is an entirely original design. Whether it is equally practical remains to be seen. The main difficulty, we apprehend, will be found in the circumstance that the outlines of the student's sections will not correspond to those in the book; and hence, instead of receiving an aid to the making of a drawing, the student will be met by an obstacle to be overcome before a satisfactory result can be obtained.

THE PRESCRIBER'S MEMORANDA. 16mo, pp. 301. New York: William Wood & Co. 1881.

THIS pocket-sized memorandum is one of the most valuable of a series now being published by W. Wood & Co. This is saying a great deal, considering the practical character of these works and their intrinsic value as available handbooks. The little work before us is made up of a very judicious selection of items of treatment, and the collection of practical suggestions regarding the management of the commoner diseases. It is full of valuable and reliable prescriptions, and is evidently prepared by a practitioner of large experience and sound judgment. The practical value of the book is out of all proportion to its size and pretension.

*Stated Meeting, June* 8, 1881.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

THE REPORT OF THE COMMITTEE ON MICROSCOPY

was read by DR. WILLIAM HENRY PORTER, Chairman.

The tumor removed from the nates and presented by Dr. Lewis H. Sayre, at a stated meeting, held March 9, 1881, was found, upon microscopical examination, to be composed principally of dense fibrillated connective tissue, arranged in a very irregular manner, as commonly seen in fibrous tumors. At points there was some evidence of an inflammatory action, in the shape of zones of round corpuscles. No cartilage-cells were found in any of the sections. The growth may, therefore, be regarded as a fibroma.

The tumor connected with the superior maxillary bone, and presented by Dr. C. K. Briddon at a stated meeting, March 13, 1881, was, upon microscopical examination, found to be epithelial in character. From the concentric arrangement of the epithelial elements into the so-called nest it was regarded as epithelial carcinoma.

Signed, WILLIAM HENRY PORTER, M.D.,
GEORGE L. PEABODY, M.D.,
ANDREW R. ROBINSON, M.D.

ANEURISM OF BOTH VERTEBRAL ARTERIES.

DR. W. M. CARPENTER presented a specimen with the following history, furnished by Dr. Anderton, House Physician at Bellevue Hospital:

J. D——, aged thirty, Scotch, was admitted to the hospital October 5, 1880. His previous history was that he had the initial lesion of syphilis seven years before, which was followed by secondary manifestations of the disease. In February, 1879, he had facial paralysis on the right side, from which, so far as he was able to judge, he entirely recovered. Late in September or early in October, 1880, he noticed

that he saw double, and soon afterward it was noticed that his right eye was turned inward, and he was unable to rotate it outward.

On admission there was internal strabismus affecting the right eye, deafness in the right ear, and loss of voice. There was paralysis of the right vocal cord, and the optic papilla was prominent.

On October 17th, facial paralysis on the right side returned, and he was unable to close the right eye. Iodide of potassium was administered in gradually increasing doses, until seventy-five grains three times a day were given, and with marked benefit.

On April 17, 1881, he had an epileptiform convulsion. The iodide of potassium was discontinued, and the bromide of potassium substituted.

On April 24th the note was that he had not had another convulsion, and was again able to do his work about the doctor's room. On April 29th he complained of headache, and felt dull. On May 9th he was obliged, on account of headache and general feeling of discomfort referable to the head, to discontinue his care of the room. On April 15th he still complained of headache, and on April 17th it was noticed that he was getting more and more stupid, and could be aroused only with difficulty. From that date he remained stupid, became delirious, and died May 23, 1881.

At the autopsy there was found general dryness and congestion of the brain. There was notable thickening of the pia mater around the sixth and the seventh nerves on the right side. There was aneurism of both vertebral arteries (about three-eighths of an inch in diameter) as they joined to become the basilar. There was a gummy growth surrounding the right vertebral artery, and thrombosis of the vessel below the aneurism. There was a gummy tumor, an inch in diameter, in the anterior lobe, pressing upon the middle cerebral artery on the right side. There was extensive softening in the temporal lobe on the left side. There was atrophy of the crico-arytenoideus muscle on the right side. Microscopically (Dr. W. H. Welch), gummata attached to the arteries were found in abundance throughout the brain. The liver contained a few gummy growths. The other organs were apparently normal.

Dr. Ripley referred to a peculiar grouping of symptoms in syphilitic cases; for instance, in an illustrative case there was paralysis of the right arm and the left leg, and in the case just reported there was paralysis of one muscle of the larynx and one ocular muscle. He thought that syphilitic paralysis in children could often be diagnosticated by this peculiar grouping of symptoms.

### SUPPURATIVE PERICYSTITIS.

Dr. Carpenter also presented a specimen removed from the body of a professional beggar aged sixty-six, who died in Bellevue Hospital. No history could be obtained. At autopsy there were found congenital phimosis, with balanitis, narrowed meatus urinarius (No. 8, American scale), dilated fossa navicularis, slight bar at the neck of the bladder, a bladder with hypertrophied walls and diminished calibre, dilated ureters, dilated pelves, surgical kidneys, and pericystitis. When the specimen was removed, and the inner surface of the bladder made tense, pus welled up from a multitude of small openings which communicated with suppurating cellular tissue in front and upon the sides of the bladder, and extended up the sheath of the right rectus muscle, and the question arose, whether the pericystitis was primary or secondary to the cystitis. Dr. Carpenter was of the opinion that it was secondary to, perhaps merely coincident with the cystitis, and that the condition of the bladder depended primarily upon the condition of the genito-urinary canal in front of it. One of his colleagues, however, expressed the opinion that the pericystitis was primary, and the cystitis secondary.

Dr. Ripley thought that extensive pericystitis was not likely to occur without some special cause, and that probably it was the secondary affection in this case.

The President thought that pericystitis was found almost exclusively in connection with some operation about the bladder, or some disease which had called for an operation. Whenever a permanent stricture existed, dilatation and hypertrophy of the bladder were quite sure to follow, and subsequently dilatation of the ureters, then dilatation and inflammation of the pelves of the kidneys, terminating, perhaps, in destruction of the entire kidney. In the specimen presented, if there was escape of pus from without into the bladder, it was hardly natural to suppose that consecutive dilatation of the ureters, with pyelitis or pyo-nephrosis, would occur. One could often explain dilatation of the bladder on the ground that there was a narrowed meatus, producing spasmodic contraction at the neck of the bladder. In the specimen presented there was undoubtedly an actual bar at the neck of the bladder, composed mostly of mucous membrane. In a large number of cases, where tight stricture existed in the deep portion of the urethra, with dilatation behind, and abscess formed there, the operation should not be simply to cut into the dilated part behind the stricture, but to do the operation for stone—entering the bladder behind the prostate—thus relieving all the surrounding tissues of the pus by which they might have become infiltrated.

Dr. Post referred to a case in which he assisted the late Dr. Gurdon Buck in an operation for removal of a vesical calculus, and the patient died of pericystitis.

### SARCOMA OF THE THIGH.

Dr. A. C. Post presented the thigh removed from a man aged forty years, a Scotchman, who had enjoyed good health until a short time before the appearance of the tumor. Two weeks before he first noticed the swelling, he received a fall while engaged in the amusement of curling upon the ice, but did not injure his thigh. There was no apparent connection between the fall and the development of the tumor, which he first noticed as a small swelling in the lower part of the thigh, in the early part of January, 1881, and it had increased rapidly in size until the operation. The tumor was soft, semifluctuating in its feel, and the sensation of fluctuation was such that, after the patient was upon the table and the tourniquet had been applied, some of his colleagues suggested it was a cyst containing fluid, and that it would be proper to make an explorative incision, which was done, and a considerable quantity of coagulated blood was found beneath the integument and fascia. Some of this material was examined under the microscope by Dr. L. A. Stimson, who expressed the positive opinion that it was organized tissue. Dr. Post then proceeded with the amputation. On examination, it was found that the growth was not primarily connected with the periosteum, but had developed in the muscular tissue of the thigh. It had, however, become somewhat adherent to the periosteum, and there were portions of

the bone which seemed to be bare. The tumor was about twelve centimetres long, and its circumference was somewhat greater than its length. The patient was doing well. There was no glandular enlargement in the groin. The stump was treated by Dr. Markoe's plan of through drainage. There was, apparently, union by first intention throughout, but afterward the edges of the wound separated, and there had also been a slight slough in two places. The patient's temperature had not been above 102° or 103° F., and this morning was about normal.

With reference to the case reported at the last meeting, Dr. Post remarked that there had been a proliferation at the extremity of the bone where it was amputated, and there was reason to apprehend that the disease had returned. That would have led him to propose exsection of the head of the bone, but he found that another tumor had developed, which made the case still more alarming, namely, a small growth upon one of the ribs. The patient's general condition, however, had improved since the amputation.

The President remarked that there seemed to be some organized tissue in the specimen presented by Dr. Post, in which a clot had formed, but the microscopical examination had not yet been completed. It was a question whether it was fibrous thickening with hemorrhage, or sarcoma with hemorrhage into it. He did not regard it as malignant in the sense of being carcinomatous.

Dr. Ripley remarked that fibroma would not occasion secondary deposits.

### NASAL POLYPUS (?)

Dr. D. Bryson Delavan presented a microscopic section made from a tumor removed from the nose of a boy aged fourteen years, who, so far as he was able to discover, was in good health. The tumor was about the size of a raspberry, had a dark color and uneven surface, and was attached to the right side of the nasal septum, by a well-defined pedicle about three-fourths of an inch from the nasal orifice. The boy first noticed it three months ago, but doubtless it had had a greater duration. It grew rather rapidly, and, as a result, respiration through the right nostril became more and more impeded. It was attended with some soreness, and with frequent but small hemorrhages. Dr. Delavan placed a wire snare around the pedicle, expecting to remove the tumor rapidly, but the tissue proved to be so dense that it could not be completely divided with the wire, and the operation was completed with scissors. The growth was not an ordinary nasal polypus, but belonged to a rather rare variety, of which Dr. Delavan had seen only one previously, and that was highly vascular, and gave rise to profuse hemorrhages.

The specimen presented was covered with epithelium, such as found upon the skin, a distinct stroma of connective tissue holding a large number of lymphoid cells, and a large number of blood-vessels with very thin walls, apparently sinuses. [A more complete description will be given hereafter].

Dr. J. H. Ripley presented a specimen illustrating

### CONCENTRIC HYPERTROPHY OF THE LEFT VENTRICLE; DISEASE OF THE AORTIC AND MITRAL VALVES.

It was accompanied by the following history: A. P——, twenty-four years of age, born in Hungary, single, and by trade a blacksmith, was admitted into St. Francis' Hospital, May 6, 1881. No hereditary disease in the family. The patient always enjoyed good health until two years ago, when he began to suffer from chronic rheumatism, affecting chiefly the elbows and feet. It was never sufficiently severe to prevent him from working. He had never had syphilis. Early in April last he complained of shortness of breath after slight exertion, and of pain in the precordial region. On the 20th of the same month he was suddenly seized with "a tearing pain" in the cardiac region, which was immediately followed by a dry cough, palpitation of the heart, and great dyspnœa. These symptoms, although modified, continued up to the time of his admission, when, in addition to these, he had œdema of the lower extremities, and was subject to frequent attacks of vertigo.

An examination of his chest soon after he entered the hospital gave the following physical signs:

*Heart.*—The area of cardiac impulse was increased. The apex-beat, of unusual force and of a heaving character, was seen and felt directly under and one and one-half inch below the left nipple. A strong, superficial thrill was felt during systole in the second intercostal space near the sternum on the right side. The area of cardiac dulness was increased both to the right and to the left. A loud, whizzing systolic murmur, with its maximum intensity at the right of the sternum in the second intercostal space, was heard all over the chest and with great distinctness behind on both sides, it being particularly loud in the right intrascapular region. A second systolic murmur, of a blowing quality, was heard with greatest intensity at the apex, but could be traced around to the left, and was distinctly audible near the lower border of the scapula. A feeble diastolic murmur was also recognized at the xiphoid cartilage.

*Lungs.*—There was flatness at the base of each lung, as well as entire loss of the respiratory murmur. A slight friction-sound was heard in the left axillary region.

*Diagnosis.*—Cardiac hypertrophy with aortic insufficiency and stenosis and mitral insufficiency; double hydrothorax. It was also thought, from the history, that there was present some acute endocarditis.

The condition of the patient grew rapidly worse; great œdema of the lower extremities supervened, and orthopnœa and dyspnœa hastened exhaustion. He died May 25th, nineteen days after entering the hospital.

*Autopsy* by Dr. E. C. Wendt.—Pericardial sac extended from the junction of the costal cartilage with the sixth rib on the left side to the mammary line on the right side. The pleural cavities contained about twelve ounces of clear fluid; the abdominal cavity also contained a small amount; about eight ounces of serum, holding whitish flakes, were found in the pericardial sac. The right ventricle was much dilated. The left ventricle was markedly hypertrophied—the hypertrophy being of the concentric variety. The mitral valve was thickened, and the distance from the attached to the free border one-fourth of an inch. The aortic orifice showed considerable stenosis and malformation, due probably to cicatricial contraction of the semilunar valves. A broad band of fibrous tissue extended across the aortic orifice below the attached border of the semilunar valves. The pulmonary semilunar valves and the tricuspid valves were normal. The liver was large and hyperæmic. The kidneys were normal. The spleen was enlarged and softened. The lungs were generally œdematous. The heart weighed twenty-eight ounces. Its left ventricular wall was fifteen

lines in thickness (the weight and measurement were taken nearly two weeks after the autopsy was made).

Dr. Ripley remarked that the special point of interest in the specimen was the concentric hypertrophy. A great many observers had denied the existence of such a condition. There were some, however, who acknowledged that concentric cardiac hypertrophy could exist, but he was not aware that a case of that kind had ever been recorded.

At the autopsy, the left ventricle in the specimen presented was filled with water, and found to hold about one ounce. Two days ago he closed the incision made through its wall, and then filled the cavity of the left ventricle with melted wax, allowed it to cool, then removed the mass, remelted and measured it, and found that there were eight and one-half drachms. That the wall of the left ventricle was exceptionally hypertrophied, and the cavity unusually small, was apparent.

Another interesting point was the existence of a bar across the bases of the valves, which probably gave rise to the peculiar thrill noticed during life. The cardiac muscle had been examined microscopically, and found to be normal.

Dr. Ripley thought that the obstruction to the outflow of blood must have existed for a long time, and that the regurgitation at the aortic, and also the mitral orifice, had had only a short duration. On that ground could be explained the large amount of concentric hypertrophy without dilatation.

Dr. W. M. Carpenter asked whether the heart was found in systole or diastole at the autopsy.

Dr. Wendt replied that it was found in systole.

The President remarked that it had been stated that cardiac hypertrophy without dilatation did not exist.

Dr. Ripley replied there were many who believed that it existed; for instance, Rokitansky, Skoda, Wendt, and others; and it seemed to him that there was quite as much danger of going to the other extreme and regarding the diminution in size of the ventricular as always due to contraction, as there was of making the mistake in regarding it as due to concentric cardiac hypertrophy.

It was not often that a cavity such as existed in the left ventricle of the heart presented was seen; and at autopsy it was exceedingly rare to find the heart in systole. Why was it so?

Dr. Peabody said that one reason why the heart was not found more frequently in systole at autopsy, was because relaxation incident to post-mortem changes had taken place before the examination was made.

Dr. Wendt said that several hours elapsed between death and the autopsy in Dr. Ripley's case.

Dr. Peabody thought that the condition of the heart presented was one which could be explained naturally upon the supposition that death occurred during cardiac systole. It did not seem to him that the cavity of the left ventricle was at all smaller than was frequently found at autopsy. That there was marked hypertrophy was evident, but he took issue with the statement that it was an illustration of concentric hypertrophy. He thought that it was a case of simple hypertrophy.

Dr. Ripley remarked that, according to the measurements made by Dr. Wendt and himself, the cavity of the left ventricle did not contain one-half as much as it should.

Dr. Peabody asked Dr. Ripley if he meant to say that the cavity should hold more than one ounce of fluid.

Dr. Ripley thought it should.

The President remarked that he had seen, within two weeks, a contracted heart, the left ventricle of which would not have contained more than a tablespoonful. He did not wish to state that such a condition as concentric cardiac hypertrophy without dilatation did not exist, but simply that it had been claimed, by those who had had large opportunities for operation, that hypertrophy did not exist without dilatation. Perhaps, to a certain extent, the question could not be decided.

Dr. Peabody thought that the walls of an empty heart, as situated in the body, were in contact absolutely; and that when it was opened and again sewed up, the cavities might contain half an ounce or two ounces.

Dr. Post asked if it was not fair to infer that the quantity of fluid poured into the ventricle would not nearly correspond to the quantity of blood which it contained.

Dr. Wendt said, not when the heart is in systole.

The President suggested that the question could be solved by immediately freezing a heart removed in positive systole and then making sections.

Dr. Ripley remarked that he was not speaking of the ventricular cavity when the heart laid upon its side, or as it was after it had been distended with water. No force had been used in filling the cavity. If dilatation had preceded the cavity should have contained several ounces; but, instead, the quantity was less than that contained by a normal heart.

### MULTIPLE UTERINE FIBROIDS.

Dr. E. C. Wendt presented the uterus removed from the body of a woman, aged twenty-six, who was admitted to St. Francis' Hospital, with the history of acute pleuritis with effusion, and was also menstruating. She had been married two weeks. She died on the day following her admission.

At the autopsy, made twenty-four hours after death, the lesions of acute purulent pleuritis were found. The mucous membrane of the uterus presented the usual thickening seen during menstruation, and it was reddish and succulent. In addition, there was found a polypus attached to the fundus by a distinct pedicle, and extending downward nearly to the internal os. There were, also, several subperitoneal and intramural fibroids, some of which were, apparently, undergoing calcareous degeneration. The line of demarcation between the cervix and the body was very distinct. There was a corpus luteum on the right side, in what appeared to be an excrescence projecting from the substance of the ovary; and there was corpus luteum in the left ovary of about the same size and appearance. The largest of the fibroids was of about the size of a hazel-nut.

Dr. Post doubted the existence of intramural tumors in the specimen.

### DOUBLE OVARIAN CYST.

Dr. B. A. Watson presented the uterus and its addenda removed from the body of Mina Miller, who was murdered in Guttenberg, N. J. It had been supposed that she was pregnant, but examination revealed no change in the uterus. There were two ovarian cysts, one upon each side, which were presented.

The society then went into executive session.

*Stated Meeting, June* 22, 1881.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

DR. A. B. JUDSON presented, on behalf of a candidate, a specimen of tubal pregnancy.

DR. H. N. HEINEMAN presented, on behalf of a candidate, a specimen of aneurism of the arch of the aorta.

NEUROMA—REMOVAL—SPLICING THE NERVE.

DR. F. LANGE presented a patient who had a neuroma of the brachial nerve just where it left the axilla. The tumor was removed, and by the operation the continuity of the nerve was interfered with to the extent of four inches. In accordance with the method suggested and practised by Gluck, of Berlin, he implanted, seventeen days ago, four and one-half inches of the sciatic nerve of a dog. The wound healed by first intention. Whether the case would be a success so far as restoration of nerve-function was concerned, he was unable as yet to say. Dr. Lange directed especial attention to the fact that the sciatic nerve of the dog, although the animal used was a large one, did not correspond in size with the excised nerve—it was considerably smaller. He thought that it was important to ascertain the relation, with reference to size, between the nerves of man and animals, in order that it might be determined from what species of animals nerves of the proper size might be derived for this purpose. The tumor had the appearance of a fibro-sarcoma, but the examination had not been completed.

DR. RIPLEY asked if the splice was made for the purpose of restoring nerve-function.

DR. LANGE said that it was, and that Gluck had been so successful that within a short time the function of conductibility had been restored, which he regarded as exceptional after dividing nerves, and especially after the removal of long pieces of nerves.

DR. RIPLEY remarked that the ulnar nerve had been divided, a considerable portion removed, and the conductibility had been restored. The operation was performed by Dr. Howe. Had the question been settled as to how much of a nerve might be lost and yet its function be restored?

DR. LANGE said that an inch of the trigeminus had been removed, and the function of the nerve was subsequently restored.

DR. HOWE said that, in the case to which Dr. Ripley had referred, a considerable portion of the ulnar nerve was removed, which was followed by complete loss of sensation for three months after the operation, and then it began to return, and at the end of a year sensation in the parts supplied by the ulnar nerve was good. He thought the ends of the nerve had not united, because of the amount of nerve removed and the quantity of cicatricial tissue developed at the site of the operation.

DR. T. R. CHAMBERS presented a specimen of

SUBCLAVIAN ANEURISM TREATED BY NEEDLING AND GALVANO-PUNCTURE,

accompanied with the following history: Andrew J. Wyatt, United States, aged fifty-three, married, printer. Inheritance and habits good. No syphilis. Rheumatism, one attack lasting one month in ankles, occurring twenty years ago. The first symptoms of aneurism began three years ago with pain in the little finger of his left hand, and gradually extended into the arm and whole upper extremity. In January, 1880, the subclavian aneurism had become a prominent tumor upon the left side of the neck. It had visible pulsation, thrill and bruit. The pain was chiefly referred to the upper extremity, scarcely any in the tumor itself. At times large quantities of morphine were required, and occasionally his mental disquietude required the addition of a mixture of chloral and camphor, equal parts. This proved of great service for a disturbed sleep, and calmed his maniacal tendencies. Dr. Weir examined the patient and found a continuous bruit across the manubrium, which did not seem to be cardiac, and which, taken with the patient's complaint of pain in the cervico-dorsal spine, led him to suspect dilatation of the arch. The cardiac physical signs failed to reveal any pathological changes. The tracing of the left radial pulse, obtained with great difficulty on account of the smallness of the current, yielded the usual wavy descent found with obstruction along the course of an artery. In March there was œdema of the left upper extremity, as well as of both ankles, and the consumption of morphine had reached the enormous quantity of 30 ctgr. in a single day. On March 30th he had a sudden attack of dyspnœa, and for two weeks was compelled by weakness to remain in his chair, being unable to walk, and dorsal decubitus was uncomfortable. On April 23d he had a chill, fever, and abdominal pain and swelling. The same symptoms were repeated May 31st, when the abdominal swelling assumed quite an extensive size, required surgical interference to evacuate a cupful of pus, and the diagnosis, confirmed at the autopsy, was abscess of abdominal wall.

In October last a plaster cast was taken of the shoulders and neck and a large external tumor rising above the left clavicle, between it and the trapezius behind, bounded externally by the acromial end of the clavicle and rising internally almost to the border of the inferior maxilla. There were at no time symptoms of pressure upon the trachea or carotid, and only those of pressure upon the nerves of the left cervical plexus and veins of the same region, together with a diminished blood-supply.

October 8th.—The aneurism had slightly increased in size, and showed tendency to pointing. The patient wished to try anything to terminate his sufferings.

*Needling.*—Six milliner's needles, 4.5 ctm. long, were introduced, and on the next day nine more were inserted into the tumor, care being taken to avoid the direct current. Some of the needles gave slight pain on piercing the skin, others none. After remaining imbedded in the tumor for six days, and a drop or two of pus appearing about the punctures, the needles were removed, and there was no apparent change in the aneurism.

October 24th.—There was visible pulsation and expansion in every available part of the tumor. A thrill was felt posteriorly adjacent to the neck, and a distinct bruit heard everywhere, especially over the region of the thrill. The current approached the surface in several places, and very threateningly at places of pouting.

*Galvano-puncture.*—With the kind advice and assistance of Dr. E. Evetzky and Dr. G. L. Knapp, galvano-puncture was resorted to. The apparatus employed was a Stöhrer's battery of twenty-one cells; a rheostat by which the intensity of the current could be gradually raised or lowered between a single couple and the full strength; six milliner's needles, 8 ctm. long, with their points changed to sharp, flattened spear-heads, and insulated by collodion. This coating increased their size from No. 2 to No. 4 French. Three centimetres of polished

steel was to be exposed in the tumor. This coating proved a most handsome and effective insulation.

*First seance.*—The patient being etherized, two needles were inserted parallel to each other, 2 ctm. apart. A strong galvanic current was passed through them and the poles alternated every five to eight minutes. They remained inserted for about forty-five minutes, and were withdrawn when a peculiar black-and blue appearance of the whole upper extremity was noticed. On removal, one of the needles had entirely lost its exposed steel; it had been utterly consumed, not broken off, an accident which has happened to some experimenters. The other needle was rough, black, and thinned. With their removal was an escape of gas and tarry fluid. The patient passed quietly out of the etherization and a slight change in the tumor was observed; the thrill was diminished and there was beneath one of the punctures a seeming condensation of the tumor's contents.

*Second seance.*—Since the first seance, four days ago, there has been no change in the tumor nor in the patient's condition, which is good. The patient was etherized with difficulty. A current of twenty-one cells was passed for forty minutes through two needles inserted as before. Within five minutes a scarlatinoid rash appears on the left shoulder and upper extremity. This gradually darkens and becomes black and blue, in irregular patches. The thrill disappeared. On withdrawing one of the needles a subcutaneous hemorrhage occurred, forming a secondary tumor quite as large as the aneurism. Pressure finally controlled it. After fifteen minutes' interval, two fresh needles were introduced in other places near the thin parts of the sac, and the current passed as previously, alternating every five or eight minutes, for forty minutes. On withdrawing one of the needles a bright arterial stream spurted out of the puncture, which, however, was soon controlled by pressure.

He failed to come out of the etherization, but went into a state of coma, out of which he partly emerged two days later, but with external strabismus, almost constant nausea and vomiting, and for four days severe headache, and loss of vision even to light. The black and mottled appearance of the arm gradually disappeared at the end of a week, and blebs, which had formed upon the palmar surfaces of the second and ring fingers, gradually dried up after two weeks. There were ecchymotic spots scattered over the hand and arm, which also disappeared.

On March 6th the tumor had attained to the size of a baby's head, and had three places of pouting where the sac-wall was scarcely as thick as paper. For the past fortnight the pain in the tumor had become very severe; it had formerly been confined to the shoulder, arm, and hand. The body was constantly bathed in perspiration, the mind wandered, vision was completely lost, hearing was very acute, and he refused to swallow any nourishment lest in the effort the aneurism would burst, and at 2 A.M. the upper place of pouting gave way while patient was at stool. The blood squirted across the room and struck the opposite wall. Oozing continued four hours, notwithstanding the pressure applied.

On March 9th a second rupture occurred from another place of pouting, and oozing lasted for half an hour.

On March 10th a third hemorrhage from a reopening of the upper place of pouting occurred, and it required digital pressure for an hour and a half to stop it.

March 14th, 12.30 A.M.—Patient was drawn up in bed for half an hour by the agonizing pain in tumor, when suddenly his pain was relieved and he died quietly with a slit two centimetres long in the upper and anterior part of the tumor.

*Autopsy*, made twelve hours after death.—*Body not* emaciated. Features placid. No œdema. There is a depression in the left suprascapular region, where the tumor had existed. The left upper extremity was atrophied.

*Abdomen.*—The subcutaneous adipose tissue was abundant. The muscular layers on the right of the median line, where the umbilical tumor* had presented, were thinned. The peritoneum had adhesions over a surface an inch square anteriorly over the right lobe of the liver; *none elsewhere.* There was injection and slight thickening, for a space the size of the palm of the hand, at the site of the abscess in the right lumbar region. The *vermiform appendix* not abnormal. *Intestines* the same.

*Thorax*, no adhesions. There were no signs of pressure having existed in the region of the aortic arch, upon the sternum or the spine. *Heart* in normal position, small, firmly contracted, hard, anæmic. *No hypertrophy.* The left ventricular wall seemed thinner than it should be. Muscular tissue brown. Aortic valves slightly atheromatous and thickened.

*Kidneys* both nearly of normal size. Capsules not adherent. Slight increase of connective tissue in cortex.

*Spleen* not abnormal.

*Liver* slightly large, slightly fatty.

*Aorta.*—Immediately upon leaving the valves it was greatly dilated in circumference and length throughout. Its lining membrane had numerous elevations and depressions, indurations and scars, and there was scarcely any normal appearance. There were ulcers of recent endarteritis and cicatrices. The openings of the innominate, left carotid, and subclavian, and of the descending aorta, were enlarged and atheromatous. The descending aorta was normal, except at its commencement. There was a branch given off just below the innominate artery, which probably supplied the collateral circulation to the left upper extremity. The branches were all given off near the descending aorta, the dilatation being more extensive between the aortic valves and the innominate than elsewhere.

*The subclavian artery* was given off just above the aortic opening. For 8 ctm. it was irregularly dilated and atheromatous; had two or three very small branches and blind pouches, and emptied by a constricted ring into the *subclavian aneurism*, a pear-shaped tumor about 13 ctm. long and 9 ctm. wide at its base. It extended, when distended, from the inferior maxilla to the second rib, lying upon it and the first, which was included in its cavity, and in close apposition with the carotid artery and side of the neck. Behind, it pressed upon the cervical plexus. Externally it pressed upon the scapula and clavicle, and anteriorly upon the clavicle, which was also included for 4 ctm. distance. Both the first rib and clavicle were eroded. The sac itself was thin in places, elsewhere being strengthened by laminated blood-clots. The six punctures of the galvanic needles were readily seen, and one was in the centre of a black infiltration 1 ctm. square. There did not seem to be any connection between the blood-clots and the punctures. There were a number of dark clots adhering to the sides, which were washed off by a gentle stream of

* Reported in the New York Medical Journal, December, 1880.

water. The fatal rupture did not start from a puncture. There were a few small arterial twigs given off, and the axillary was but the size of a lead of a pencil. There were no vestiges of the previous needling operation.

*Remarks.*—This case had interest for a number of reasons. The rarity of subclavian aneurism on the left side; the long duration of the disease in its advanced condition—for the patient carried a pulsating tumor the size of an orange on the side of the neck, for two years and a half; then, a fortnight before death, its size was that of a child's head. Three hemorrhages through openings in the sac occurred during the last week before fatal rupture. The strange sequences of the galvano-puncture operation—were they sequences of the etherization, or was it blood-poison?—the clot probably being formed at one pole, to be broken up again when the current was alternated, and thus throwing, by the two seances, a large quantity of foreign matter upon the circulation? Or was it due to renal disease? The urine, examined carefully, never contained but a faint trace of albumen. The autopsy revealed a second aneurism of the arch, with extensive ulcerative endarteritis of the same; confirmed the diagnosis that the iliac abscess was confined to the abdominal wall, and showed that, notwithstanding the immense obstruction to the circulation by the two aneurisms, the heart was not hypertrophied, nor was there insufficiency of the valves.

Galvano-puncture, for the cure of intra- or extra-thoracic aneurisms, has scarcely had a trial in this country. In Europe it has had careful study. The first cure reported was that of Petrequin, in 1845, of a temporal aneurism. Then followed a number of failures, and the Italian Commission formed at this time were very sceptical. In 1846 Ciniselli tried it for the cure of aneurisms of the aorta. England, Germany, and France have had many of its students, and especially valuable have been the results obtained by Dujardin Beaumetz and his pupil, Dr. Laurent Robin.

Robin says: 1. It is scientific and rational, and yields practically good results. 2. It is the best of the therapeutical agents employed thus far, for it determines in an aneurismal sac the formation of a clot susceptible of organization. 3. The positive pole alone should be introduced into the tumor, to obtain a firm and resistent clot. 4. This mode of treatment, employed with all the precautions pointed out in his work,* is devoid of all fear of emboli, hemorrhage, suppuration, gangrene, or of a single unpleasant accident. Invariably it procures relief, even in desperate cases.

An old idea was that coagulation was due to inflammation of the sac surrounding the punctures; another that the electric current itself was the cause. [Dr. Smee ("Royal Soc. Trans., 1863") passed oxygen and hydrogen through an albuminous fluid and obtained a substance called fibrin.] Robin is certain that it is due to the chloride of iron and acid formation of the positive pole. It is the general agreement that the gelatinous froth of the negative pole does not tend to organization. The operation is painful, which is relieved by etherization. The gas formed during the operation is never sufficient to embarrass the patient. The needle-punctures may be so small there need be no fear of hemorrhage, especially if pressure can be applied. The current should not be less than about twenty-one cells of a Gaiffe, Bunsen or Stöhrer battery. It should gradually be increased from zero to the greatest intensity, and *vice versa*. It should be continued about five minutes upon one needle, then upon another inserted a short distance off, and so on upon several. It should *not* be alternated. When the two poles upon two needles are introduced, the action is more energetic, and the clot is formed more rapidly, but it is imperfect and feeble. No clot is formed by the negative needle, but that of the positive is solid, resistent, and adherent. It seems plausible that, in the case just cited, the induration within the tumor was changed, when the current was alternated, from consistency to a frothy, gelatinous, and easily removable matter. Perhaps so much foreign substance thrown suddenly into the circulation was the primary cause of all the peculiar phenomena of central disturbances following the second seance.

Robin thinks the clot due solely to chemical changes, and suggests always using iron or steel needles, rather than platina, zinc, or silver, the chloride of iron and acid formation at the positive pole being the prime factors. The clot, he says, "is coagulation of albumen, solidification of fibrin, and exudation of plastic lymph."

With regard to the apparatus, it is necessary to have such as a Gaiffe or Stöhrer battery of about twenty-one small elements. Such have the least amount of thermic action and the greatest intensity—electro-chemically decomposing and destroying. The battery of large surface elements is useful in galvano-cautery, the smaller in coagulating and dissolving, according as the positive or negative pole be used.

An extensive bibliography of the subject may be found in Robin's work.

The statistics of the operation are easily summarized. Amelioration refers to lessening of the pulsation, arrest in development of the tumor, relief of pain, partial or complete, and dispersion of the dyspnœa. In most of the cases, probably there was but one seance; in others, it was repeated, even a dozen times.

The figures opposite amelioration might be much larger, but are omitted in many cases.

* De l'électro-ponction dans la cure des anévrysmes intra-thoraciques. 1860.

Comparing it with ligation (Norris's table of ligatures) with 33.1 per cent. of death, galvanism had but 12.9 per cent., and this with the bad success of Ciniselli. Hutchinson in 1856 compared it with compression and found 25 per cent. success and 29 per cent. failure in compression; 24 per cent. success and 30 per cent. failure in galvanism.

SYPHILITIC MENINGITIS—DIFFUSE CHANGES IN THE SPINAL CORD—CYSTITIS AND PYELITIS.

DR. WM. H. PORTER presented a specimen with the following history:

W. M., aged fifty-nine, married, and a druggist, was admitted to the Presbyterian Hospital, December 18, 1880. Twenty years previously he had contracted a chancre, and secondary symptoms followed. His habits were temperate as regards alcohol, and his general health had seemed good, notwithstanding his syphilitic infection. The first serious trouble that he had, dated back three months before his admission. At that time he fell down-stairs, striking upon his head, and was unconcious for several hours, but recovered promptly and had no further unpleasant symptoms until a week before admission, when retention of urine caused him to call a physician.

On admission to the hospital his temperature was 102° F. and pulse 120. When standing he was dizzy if the eyes were closed, and his walk was ataxic. No paralysis of any muscles. Dynamometer showed no difference in hands. No pain, but rather cutaneous anæsthesia. His speech was thick, and deafness increased gradually from the date of his attack. The pupils responded promptly and equally to light. His tongue was coated and breath offensive. The tibiæ were very tender. The average quantity of urine was twenty-two ounces, and microscopic examination showed pus in large quantities. The reaction strongly alkaline. His water was drawn three times daily, and the bladder was washed out with a dilute solution of nitric acid (acid. nitric. dilut., ℥j. to aqua ʒ j.) Potass. iodidi was given internally. On December 22d the patient lost control of his anal sphincters. On December 24th, patient developed hiccough. His temperature had fallen to normal, but pulse remained rapid. At 10.30 P.M. he fell into a comatose condition; temp. 101° F.; pulse, 100; respiration, 20. The kidneys continued to secrete water freely, but the catheter had still to be used. The coma gradually deepened, and he died at 9 o'clock A.M., December 25th.

*Necropsy*, December 26, 1880.—Two scars were observed on the penis, and a large copper-colored cicatrix existed just above the internal malleolus of one leg.

*Thoracic cavity.*—The heart weighed eleven ounces; substance did not appear abnormal. All the valves were thickened and exhibited clearly the usual lesions of endocarditis. The lungs were slightly adherent at the apices, at which point was the usual localized condensation of tissue found in connection with old pleuritic adhesions. Both organs congested and œdematous.

*Abdominal cavity.*—Spleen normal, both in weight and consistency. The stomach and intestines were not opened, as they did not indicate, externally, any noteworthy signs of morbid changes.

*Genito-urinary tract.*—These parts were specially interesting. The bladder showed evidence of cystitis, was sacculated and distended, containing at the examination 130 c.c. of milky-looking urine. Both ureters greatly dilated, the right especially. The pelves of both kidneys were dilated, the right containing pus. The mucous membrane red and dotted with ecchymotic spots. The whole superficies of the right organ was marked by small, yellowish, solid deposits of a cheesy appearance. On microscopic examination these collections were found composed of rounded corpuscles resembling leucocytes, with an admixture of molecular debris and oily matter. The liver weighed fifty-six ounces, and showed no special evidence of disease.

On removing the calvarium, an excess of serous fluid escaped, and all the vessels of the meninges were found unduly distended with blood. Some difficulty occurred in removing the bone, because it was firmly adherent through the dura, with the pia mater. These membranes were also abnormally thickened and opaque in patches, most noticeable at the base and in the Sylvian fissures. Further, the brain-substance was more than usually vascularized, the left lobe of the cerebellum and the medulla showing this condition most prominently.

In removing the cord the pia mater was found noticeably thickened. In addition, the microscope showed that there was an extension, inwardly from the pia, of newly formed connective tissue, while the vessels were contracted, hypertrophied as to their coats, and distended with blood. In many places there was a diffuse collection of leucocytes in the contiguous tissue. Two pathological conditions were especially noteworthy: one the disseminated foci in the right kidney, and the other the vascular changes in the cord. The former were probably gummata, the latter a hyaline change in the muscles, possibly amyloid, and due to syphilis. The case was specially interesting in connection with the present interest in syphilitic lesions of vessels. Sections from the cord, when compared with others, showed a marked thickening of the vessels and interstitial tissue. The thickening of the vessels and general sclerosis seemed to be the only way in which the partial paralysis and lesions of the genito-tract could be explained. A number of observers have noticed and recorded a similar thickening of the cerebral vessels.

DR. GEORGE L. PEABODY presented a specimen of

ULCERATIVE ENDOCARDITIS,

with the following history:

E. W. C., aged twenty-three years, native of the United States, bookbinder, was admitted to the New York Hospital, April 20, 1881. His mother died of consumption. No history of venereal disease or of articular rheumatism. He was perfectly well up to three weeks ago, when, upon returning from New Orleans, he had a chill followed by fever, sweating and great prostration. Four days later he had a second chill of similar nature. These symptoms were followed by great prostration, emaciation, and feebleness, anorexia, and general stiffness in joints. He has had slight cough, and on two occasions noticed dark, clotted blood in the sputa. No pain in the chest or præcordium, and no shortness of breath. No night-sweats or swelling of feet; urine highly colored; bowels regular.

*On admission.*—Pulse, 100; respiration 24; temperature 103.6° F. Emaciated; very anæmic; skin hot, dry, sallow; no eruption; some tenderness and pain in knees and ankles, and also in legs; no œdema; tongue thickly coated and moist; pulse soft and compressible; examination of lungs negative; a loud double murmur was heard over the apex of the heart; apex-beat displaced below and outward. He was put upon salicylic acid, gr. xv.

every two hours. Subsequently Bland's pills were given; urine normal. For a week his symptoms did not change, his temperature varying between 101° and 104° F., there being always an evening exacerbation.

April 29th.—He complains of pain in the precordial region, with dyspnœa and palpitation. Has emaciated rapidly. Salicylic acid was discontinued, and he was given quinine and quebracho. His joints remained painful and tender, and now became swollen, but never red. The area of precordial dulness increased toward the left. There was no precordial sound.

May 3d.—Coughed much last night, and this morning has viscid expectoration, with blood-streaks. Has had no chills since admission. Temperature is unchanged. Sibilant and sonorous râles heard over both lungs, with a few râles behind, low down.

May 5th.—Tubular breathing and other signs of consolidation were noticeable from apex of right lung to nipple line. He was much prostrated, and losing ground every day. He was freely stimulated without benefit, and continued steadily sinking, with temperature elevated as before, until May 21st, when he died at 5.30 A.M. The heart-murmurs remained unchanged.

*Autopsy*, May 21st.—There were 250 c.c. of serum in the pericardium, but the object of chief interest was the heart. The posterior segment of the mitral valves had an enormous mass of recent vegetation adherent to it, causing it to appear rather more than a centimetre in thickness. The anterior segment was in a similar condition, but less thickened. On removing some of this mass the valve was seen below, deeply ulcerated. The chordæ tendineæ were many of them entirely eroded. The left ventricle was somewhat dilated. In both lungs there were extensive areas of catarrhal pneumonia. There was nothing else in the autopsy bearing upon the clinical features of the case. The microscopic examination of liver, kidneys, and lungs revealed no micrococci. He was inclined to regard the case as one of ulcerative endocarditis, in which the character of the symptoms was typhoid rather than septic. Like many of the cases already recorded, this one was associated with pneumonia, and, unlike many of them, it was associated with rheumatism. The rheumatism, however, did not develop until after the chills and fever, which ushered in the endocarditis.

Dr. Peabody also presented a specimen of beginning

ANEURISM OF THE HEART,

which was removed from the body of a man seventy-nine years of age. The aneurism was situated in the apex, its favorite location; the man suffered from dyspnœa and palpitation, and died suddenly.

Dr. Peabody also presented a specimen of

PRIMARY CANCER OF THE LIVER,

removed from the body of a woman fifty-seven years of age, who had given a distinct history of pain in the hepatic region during the last eighteen months; but there was no tumefaction in that region. The gastric symptoms were slight. The liver was not increased in size. The cancerous deposits were chiefly in the interior of the organ. The stomach was normal. The only secondary deposit was in the mesenteric glands.

Toward the close of life there was marked jaundice. No centre of infection in any of the large biliary passages.

Dr. V. P. Gibney presented a child, five weeks old, with

CONGENITAL DISLOCATION (?) OF THE LEFT TESTICLE.

It was without history. There was no body in the left side of the scrotum, but above and toward the perineum a body with cord attached could be distinctly felt.

Dr. A. Jacobi remarked that the left half of the scrotum was smaller than the right—did not seem so well developed. The testicle was perhaps a little larger than normal, and it seemed to be attached laterally, probably by inflammatory processes, intra-uterine, and therefore not suspended in the scrotum. If his explanation was correct, it would show that the scrotum ceased to grow as soon as the inflammatory process took place.

Dr. Lange thought there was some effusion around the body, and that it was not adherent.

CYSTO-SARCOMA (?) OF THE BREAST.

Dr. A. Jacobi presented a tumor removed from the left breast of a girl sixteen years of age. Probably it was of old standing. He presented it on account of its size. It weighed 545 grammes. There was no history of malignant disease in the family. The mass contained a number of cysts, and had the gross appearance of cysto-sarcoma.

Dr. Heineman presented specimens and microscopic slides of three cases of

TUBERCULAR PERICARDITIS.

The first was a large transverse section of the parietal and visceral pericardium and heart-wall, prepared by Professor F. Delafield, who obtained the specimen from the body of an old man, who died of chronic dysentery. The disease was not suspected during life.

The second consisted of the microscopic slides from specimens obtained at an autopsy made by Dr. T. Mitchell Prudden, on the body of a middle-aged man, whodied of chronic Bright's disease. A few old caseous nodules were found in the lungs. In this case also the disease was likewise not suspected during life.

The third was a heart, which was accompanied with the following history:

A. S., aged forty-two, born in Germany, single, and a fireman, was admitted to the Roosevelt Hospital December 7, 1879. His family history was good, and he denied syphilis and rheumatism. He had been a moderate drinker. Except for a slight attack of jaundice, six years previously, he had been well up to two weeks before admission, when, after exposure, he was seized, without a chill or other constitutional disturbance, with cough and mucopurulent expectoration. At the end of a week he was compelled to cease work, and he then suffered from loss of appetite and abdominal cramps, and, a few days later, from dyspnœa, cardiac palpitation, and weakness.

Upon admission he was well nourished, his appetite was good, and he had moderate cough, with expectoration and much dyspnœa. Examination revealed evidence of fluid in right pleural cavity and increased area of hepatic dulness. Urine, 1030, acid, with a trace of albumen. From December 8th to December 31st his temperature ranged between normal and 102° F. The dyspnœa and the fluid in the pleural cavity gradually disappeared, and on January 7th he left the hospital, having gained strength and color, but having still some cough and weakness.

On March 31, 1880, he was readmitted, stating that, after exposure six weeks previously, his cough

grew worse, dyspnœa developed, his urine became scanty, and micturition frequent; his abdomen became swollen, and three days ago had œdema of the face, feet, and legs. He was able to work, and had a good appetite up to one week ago. Now he has a dull epigastric pain. Urine, 1030, with a trace of albumen. Dulness over the right chest. April 27th.—Has prolonged expiration over both apices, and friction-râles over both lungs. Has dyspnœa, slight cough, œdema of feet and legs, and is losing flesh and strength. In May, hectic, night-sweats, severe cough, inability to lie on left side, and headache followed. In June, hyaline casts and increase of albumen to fifty per cent. in the urine. On June 22d the apex-beat of the heart could not be made out; heart-sounds feeble, growing weaker. July 2d.—Pericardial friction could be felt by the visiting physician, and pericardial friction-sounds heard. A week later (July 9th) no friction-sounds could be heard, although the heart sounds were audible in the normal position, but loudest to the right of the sternum. July 10th he was delirious, and August 1st he had a convulsion, became comatose, and died.

During April his respiration varied from 24 to 36, and his temperature from 98½° to 100½° F. During May his temperature varied from 98½° to 102¾° F. During June his temperature was normal. During July his pulse varied from 72 to 144; respirations from 26 to 64, and temperature from 98° to 102° F., but was normal during the last week.

*Autopsy.*—Body emaciated.

*Brain.*—Pia mater much thickened, opaque, and adherent in places to the dura mater; increase of serum beneath it; lateral and third and fourth ventricles dilated, and contained increased quantity of serum. Upon the under surface of the brain, over anterior portion of anterior tip of temporal lobes were erosions of brain-substance, with yellowish gelatinous infiltration.

The tip of the temporal lobe, and the optic thalamus with its immediately adjacent tissue, appeared to be softened.

*Heart.*—Very great thickening, with adhesion throughout of visceral and parietal pericardium. The right and left ventricular cavities were reduced to less than half their normal size, with degenerated and atrophied walls. The mitral valves were somewhat thickened.

*Lungs.*—The costal and pulmonary pleuræ were enormously thickened and adherent throughout on both sides. Upon the left side the thickened pleura was nearly three-fourths of an inch thick, and had enclosed between its layers considerable lymph, gelatinous in appearance, and between the pleura and diaphragm a large quantity of flocculent serum. Fibrous nodules were scattered through both lungs.

*Liver* cirrhotic and increased in size.

*Spleen* much enlarged.

*Stomach.*—Chronic gastritis.

*Kidneys.*—Normal size; striations not well marked; appear fatty.

*Microscopic examination* in all of the three cases above referred to revealed giant-cells and tubercula granula in the visceral and parietal deposit, but not in the heart-muscle.

Reference was made to the recent editorial, in the London *Lancet* of May 28th, upon the subject. Whether tubercular pericarditis was a primary or a secondary lesion was a question which had not been decided. Tubercles were found in other organs of the body in Dr. Prudden's case and in his own, but in Dr. Delafield's case none were discovered.

Dr. Ripley suggested that the symptoms before the occurrence of the friction-sound might have been due to myocarditis.

Dr. Heineman remarked that the man had disease of the kidneys and also pleurisy, which would account for many of his symptoms; and besides, he had a normal temperature during June, while in April and May it varied from normal to 102° F. In June the heart-sounds were lost, and in July the pericardial friction-sound heard, and at the same time there was a rise in temperature, but during the last week in July it was again normal. So it would seem that the most prominent portion of the heart-lesion took place in July.

The presentation of the testimonial to Dr. George F. Shrady then took place, Dr. A. Jacobi representing the society, after which the society went into executive session.

# Correspondence.

## THE PROGRESS OF NEUROPATHOLOGY.

To the Editor of The Medical Record.

Dear Sir—In the instructive report of the Proceedings of the International Medical Congress, published in the Record for September 3d, no less than two papers are mentioned as read before the Section on Mental Diseases which, as reported, purport to establish certain facts in neuropathology, demonstrably anticipated on this side of the Atlantic. From the necessary brevity of your report, it is of course impossible to say whether the American observations were ignored or not, by those reading the papers referred to. Still I hope I may ask for space for the following statement of facts.

I. Dr. A. Foville is reported as discriminating between two forms of expansive delusions, each characterizing some special forms of insanity. In the January number of the *American Journal of Nervous and Mental Diseases* will be found an article on the subject of insane delusions, by myself, which distinctly sets forth each of the criteria claimed by Foville, and is in its conclusions identical with the paper of the latter, which was read eight months after mine was published.

II. Dr. Savage is stated to have rendered good service to pathology in drawing attention to the changes found in nerve-tissues after the action of alcohol on them. It is difficult to conceive that Dr. Savage, one of the editors of the *Journal of Mental Science*, could have overlooked the existence of the following papers, several of which were extensively noticed in the journal of which he is the editor:

*First.*—My paper on "Progressive Paresis" in the *American Journal of Nervous and Mental Diseases* for 1877, in which I said that "many authors have registered and even photographed the results of the reaction of absolute alcohol (leucin and cholesterin precipitates) as lesions characteristic of progressive paresis.

*Second.*—A paper on "Reform in Scientific Psychiatry," which attacks the character of the scientific or pseudo-scientific work done at Utica, on the basis of the same facts that Dr. Savage advances, in 1878.

*Third.*—A paper published in the same journal the year after, in which I offered to manufacture the lesions photographed at Utica, before the American Association of Asylum Superintendents or a committee of that body, and to do so in healthy animal brains.

*Fourth.*—A paper, published in the *Chicago Medical Review* for June 20, 1880, of which I send you a copy, and which contains a full explanation of the microscopical and chemical nature of the artificial precipitates, and the manner of their production; and which specifies the photographs taken at Utica and Oshkosh in which they are to be seen.

I write this less on my personal account than to show that American psychiatry was represented at the Congress, however unrecognized, and that the representation, such as it was, came without the asylum circle.

Respectfully, E. C. SPITZKA.

130 EAST FIFTIETH STREET, NEW YORK.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September* 11, 1881, *to September* 17, 1881.

BROWN, P. R., Capt. and Asst. Surgeon. Granted leave of absence for one month. S. O. 210, A. G. O., September 13, 1881.

SKINNER, J. O., Capt. and Asst. Surgeon. To proceed to Fort Verde, A. T., and report to the Post Commander for duty as Post Surgeon. S. O. 101, Department of Arizona, September 2, 1881.

REED, WALTER, Capt. and Asst. Surgeon. Assigned to duty with Light Battery "A," Second Artillery, ordered to leave Washington Barracks, D. C., on September 20th and march to Yorktown, Va. S. O. 165, Department of the East, September 16, 1881.

BURTON, H. G., Capt. and Asst. Surgeon. To accompany Light Battery "C," Third Artillery, as medical officer, on its march from Fort Hamilton, N. Y., to Yorktown, Va., *via* Trenton, N. J., Philadelphia and Columbia, Pa., Baltimore, Md., and Washington, D. C.—and remain with it until further orders. S. O. 163, Department of the East, September 14, 1881.

## Medical Items and News.

EXAMINATION OF CANDIDATES FOR U. S. MARINE HOSPITAL SERVICE.—A board of surgeons for the examination of candidates for appointment in the Marine Hospital Service has been appointed to meet in this city on Monday, October 10th. Surgeons Long, Purviance, and Sawtelle have been detailed as members of the board. There are several vacancies in the grade of assistant surgeon, for which there are only a few applicants.

AN ALBANY DOCTOR, Dr. L. T. Merrill, absconded recently. He left a wife and child, as well as many creditors. Dr. Merrill had once been in good practice, but has gradually lost it through his dissipation.

FIGHTING THE QUACKS.—At a meeting of the Luzerne County Medical Society, at Wilkesbarre, Pa., September 14th, it was announced that thirty physicians out of one hundred and forty have not registered according to law. The secretary was instructed to present their names at once to the District Attorney, and to see that he takes such action in each case as the law requires.

OFFICIAL BULLETIN OF THE AUTOPSY ON THE BODY OF PRESIDENT GARFIELD.—The following official bulletin was prepared by the surgeons who have been in attendance upon the late President:

By previous arrangement a post-mortem examination of the body of President Garfield was made this afternoon, in the presence and with the assistance of Drs. Hamilton, Agnew, Bliss, Barnes, Woodward, Reyburn, Andrew H. Smith, of Elberon, and Acting Assistant Surgeon D. S. Lamb, of the Army Medical Museum of Washington. The operation was performed by Dr. Lamb. It was found that the ball, after fracturing the right eleventh rib, had passed through the spinal column in front of the spinal cord, fracturing the body of the first lumbar vertebra, driving a number of small fragment of bone into the adjacent soft parts, and lodging below the pancreas, about two inches and a half to the left of the spine, and behind the peritoneum, where it had become completely encysted.

The immediate cause of death was secondary hemorrhage from one of the mesenteric arteries adjoining the track of the ball, the blood rupturing the peritoneum, and nearly a pint escaping into the abdominal cavity. This hemorrhage is believed to have been the cause of the severe pain in the lower part of the chest complained of just before death. An abscess-cavity, six inches by four in dimensions, was found in the vicinity of the gall-bladder, between the liver and the transverse colon, which were strongly adherent. It did not involve the substance of the liver, and no communication was found between it and the wound.

A long, suppurating channel extended from the external wound, between the loin muscles and the right kidney, almost to the right groin. This channel, now known to be due to the burrowing of pus from the wound, was supposed during life to have been the track of the ball.

On an examination of the organs of the chest evidences of severe bronchitis were found on both sides, with broncho-pneumonia of the lower portions of the right lung, and, though to a much less extent, of the left. The lungs contained no abscesses, and the heart no clots. The liver was enlarged and fatty, but not from abscesses. Nor were any found in any other organ except the left kidney, which contained near its surface a small abscess about one-third of an inch in diameter.

In reviewing the history of the case in connection with the autopsy, it is quite evident that the different suppurating surfaces, and especially the fractured, spongy tissue of the vertebræ furnish a sufficient explanation of the septic condition which existed.

## SANITARY ADMINISTRATION AND THE HYPOTHESIS OF EVOLUTION.

By HENRY M. LYMAN, A.M., M.D.,

PROFESSOR OF PHYSIOLOGY AND OF DISEASES OF THE NERVOUS SYSTEM, RUSH MEDICAL COLLEGE, CHICAGO, ILL.

### PART I.

My attention, long enchained by more important things, has just now been directed to an interesting paper from the pen of Dr. Chaillé, of New Orleans, read last December before the American Public Health Association. It appears that the sanitary hierarchy of our land had been considerably flustered by a rumor that the doctrines of evolution stand in flat contradiction to their favorite plans for the erection of boards of health, etc., throughout the country. Dr. Chaillé was, therefore, requested to defend these organizations against the supposed assaults of Herbert Spencer and other ill-conditioned reprobates of similar stripe.

In this effort the doctor has done a real service by showing again what I had previously indicated (THE MEDICAL RECORD, November 8, 1879), that the doctrines of evolution, as enunciated by Mr. Spencer, notably in his work on social statics, do not in any way conflict with the establishment of official organizations charged with the care of public health. No philosopher objects to the legitimate exercise of such authority. All are agreed, in the language of Mr. Spencer, "That it comes within the proper sphere of government to repress nuisances. . . . He who contaminates the atmosphere breathed by his neighbor is infringing his neighbor's rights. Men having equal claims to the free use of the elements—having faculties which need this free use of the elements for their due exercise—and having that exercise more or less limited by whatever makes the elements more or less unusable, are obviously trespassed against by any one who unnecessarily vitiates the elements and renders them detrimental to the senses; and, in the discharge of its functions as protector, a government is obviously called upon to afford redress to those so trespassed against."

This paragraph is quite sufficient to indicate the true position of Spencer and of his disciples relative to the functions of government in the matter of public health. Its perusal clearly shows the groundless character of the charge that evolutionists are opposed to boards of health and sanitary officials. It renders entirely unnecessary the insinuation that Spencer's caustic criticism of such people was simply the expression of "certain immature views at the very dawn of his philosophical career, in 1850," which he had probably modified in 1864, and had, very likely, abandoned in 1880. The manner in which his views concerning social science have been modified is very well understood by those who have made themselves familiar with the progress of his thought during that period; and their modification is not at all in the direction which Dr. Chaillé would like to have us believe. Philosophers make no objection to the exercise of sanitary authority within the legitimate sphere of government. It is only when the agents of government ignorantly attempt to transcend that legitimate sphere that objections arise and philosophers find themselves constrained to pour out the vials of scorn upon offenders against that great law of equal freedom which is yet so imperfectly comprehended by the army of office-holders and office-seekers. The boundaries of the legitimate sphere of their activity I have elsewhere defined with sufficient precision (THE MEDICAL RECORD, November 8, 1879, p. 437); but these are truths which need much repetition, and I will reiterate the doctrine then urged: "In every well-ordered state there should be a medical officer to supervise the public relations of citizens, and to act as the adviser of the government in sanitary affairs. It should be his duty to prevent all damage to the health of citizens from the condition and use of the public property of the commonwealth. He should be prepared to act intelligently and promptly in all those sudden emergencies to which the ordinary existence of the community cannot be readily adjusted—such as an invasion by cholera or yellow fever, or the plague. But it should be clearly understood that for all the ordinary conditions and incidents of the life of a commonwealth the ordinary resources of the community are sufficient. Sanitary officials must cease their efforts when the line which divides the public life of the citizen from his private life has been reached. Otherwise, their control becomes at once intrusive, vexatious, and productive of evils greater than those which they seek to prevent."

The real cause of the contempt in which so many of our professional sanitarians are held by Spencer and his disciples, has, it is evident, not been touched by Dr. Chaillé. It lies just here—in their frequent transgression of the line which separates the public interests of citizens from their private relations. They are too anxious to do for people what people can better do for themselves. They are too ambitious and anxious for the immediate perfection of mankind. Instead of waiting patiently upon the unerring and orderly methods of normal evolution, which, as Spencer has abundantly shown, though at any given moment yielding results far short of ideal perfection, are the best possible arrangements for each unit of time, they are impatient to reconstruct society in accordance with the crude notions which may chance to be uppermost in their brains. The consequence of this temper is that the present attitude of our professional sanitarians is identical with the position occupied by those mediæval ecclesiastics who taught that religion was the most valuable possession of mankind. They esteemed the doctrines of the church so highly that they thought it right to establish an inquisition whose familiars should be everywhere, protecting men against wickedness, and visiting with all the terrors of the law every one who dared to differ from the fashionable dogmas of the church. In a precisely similar manner the great ambition of these modern enthusiasts displays itself in the substitution of the word *health* for *religion*, and in the attempt to erect a vast hierarchy of sanitary officials, occupying "every hamlet, village, town and city of the country, subordinated to and controlled by county, municipal, or State boards of health" (Gihon: "Trans. Am. Pub. Health Ass., 1880," p. 24), and busied with the supervision of copulation, with the suppression of free thought and action among physicians, and, too often, with the diffusion of scientific error among the people. Under these "highly paid experts" the members of the medical profession are to be compelled by fines and by imprisonment to enter a condition of slavery, rendering their unpaid services as spies and registrars, and what not, for the aggrandizement of their lords, the sanitary officials. Against such a degrading despot-

ism it is the duty of every intelligent man to raise his voice in earnest protest.

That this is no merely fanciful apprehension, is shown by the following extract from a recent daily paper, which of course will be stoutly denied by all parties concerned:

"The dispensary in the city of —— has just been closed by an order from the Board of Health, for the want of sufficient funds to maintain it. It seems that the expenses connected with the Health Department of —— have been enormous, and increasing each year. There has been what is generally known as a Board of Health ring, who have run matters to suit themselves. They have kept in position a large number of supernumeraries for political purposes. The college and other charitable institutions of the city have made propositions to the city to take charge of the poor, but the ring have always opposed every proposition made, because it would throw a number of them out of employment. One of the city physicians has a very large practice among the demi-monde, and claims to know every fancy woman in the city. He often has little matinées of the class that wear heavily starched underwear. It is pretty well understood that all the city police, employés, and bummers generally, in the vicinity of the health office, get medicines free from the city dispensary."

It would probably be too sweeping a charge to assert that these are the people who shape our sanitary legislation, who vote for the suppression of syphilis by the State, and who denounce without stint all criticism of their doctrines and proceedings. For these, as well as for other reasons, Herbert Spencer must still be accepted as the most satisfactory sanitary critic who has yet arisen.

Passing, now, to the second division of Dr. Chaillé's paper, I find myself arraigned for castigation in ludicrous juxtaposition with Mr. Spencer. To follow the doctor through the tangled web of probably unintentional misrepresentation which he has spun around my arguments would be an unprofitable undertaking, for it is quite evident that I have failed, in previous essays (THE MEDICAL RECORD, June 26, September 4, and November 6, 1880), to render myself intelligible to the ordinary intellect. Perhaps this is not strange, for the facts and the literature which justify my opinions are scarcely yet the common property of the profession, and it is difficult to introduce such data within the limits of a brief and hurried journal article, which must, therefore, of necessity assume a more or less dogmatic form. I will, for these reasons, endeavor once more to review the situation, striving, if possible, to throw a little light upon a difficult and neglected subject.

Dr. Chaillé objects to my suggestion, that one of the causes of the diminishing mortality and final extinction of an epidemic like the plague or typhoid fever consists in a progressive attenuation of their exciting poisons. He says: "The spreading of reproductive poisons no more diminishes their intensity, or the number of persons infected, than the spreading of fire, or of ferments, or of seeds, or of animal organisms diminish their effects." This assertion involves the assumption that the exciting poison of a virulent disease is either a process like oxidation, or an actual succession of invariable living organisms. For neither of these suppositions has any proof been yet produced. We cannot accept such a representation of the method by which small-pox is propagated as anything more than a fanciful piece of guess-work. When carefully investigated, the exciting poison of each one of the communicable diseases, as it is yielded for examination, is found, even in diphtheria and in anthrax, to be a virus, either liquid or volatile, and not a seed. The product of organized bodies, it is not itself an organized body. Time and space will not permit me here to adduce the proof of this most important distinction, but it lies at hand, where any one can investigate for himself. Being, then, a virus, it is susceptible of various modifications or dilutions, even up to actual destruction. Every virus may become more or less concentrated or attenuated. Corresponding variations in their effects, other things being equal, must necessarily follow. The experiments of Burdon-Sanderson illustrate the manner in which the activity of virulent substances may be intensified; the experiments of Pasteur show us how they may be attenuated and again intensified. The conditions of nutrition in the constituent cells of each individual largely determine the degree of intensity of the virus which they reproduce when poisoned by any given species of virus. Thus the tissues may at one time secrete a scarcely virulent substance, while under other conditions they may perish quickly in their own product. Hence the remarkable variation in the severity of the same disease occurring in different persons.

It is, of course, impossible during the course of an ordinary epidemic to trace these processes with the precision that marks a laboratory experiment; but there are certain phenomena connected with the evolution of epidemic diseases which are quite inexplicable without reference to such experiments. Let us consider, for example, the consequence of carrying the virus of scarlet fever into the tropics. A few cases are occasioned by its infective action, but the disease seldom spreads and soon disappears. The virus must either have been disintegrated by the warmth, moisture, etc., of the climate, or else its cultivation in the bodies of such patients as actually experience its influence must have so transformed its nature that its virulent energy is finally insufficient to disturb the equilibrium of those who are brought into contact with the substance. But in northern countries the fierce heat of summer is insufficient to disintegrate this virus. It would seem, therefore, more probable that the bodies of people in certain other countries do really modify the nature of the poison—do, in the language of Pasteur, actually attenuate this virus.

Again: It has been observed—more frequently, of course, before the practice of vaccination than at the present time—that epidemics of small-pox would culminate and decline; ceasing altogether before they had embraced the entire community of unvaccinated or unvariolated individuals ("Reynolds' System of Medicine," Am. Ed., vol. i., p. 156). This fact the older observers could not explain, except by the assertion that the susceptibility of the population was variable. The hypothesis of a variation in the quality of the virus furnishes a good explanation; is perfectly accordant with all the other data of science and does not conflict with the hypothesis of a variable susceptibility on the part of the individual.

Again: We know that by variolation of the cow the virus of small-pox is modified and reappears as vaccine-virus. This certainly must be accepted as an example of the attenuation or modification of a virus. That vaccine-virus itself becomes attenuated by successive transmissions is abundantly proved by the

experience of English vaccinators (Cameron: *Fortnightly Review*, May, 1881).

In view of these, and of other similar facts which might be adduced, it is very evident that the assumption of the invariability of the exciting poisons of the communicable diseases is without foundation in fact. Since we find that vaccine virus has become so far attenuated during the last eighty years—in the course of the four thousand successive cultivations to which the original Jennerian virus may have been subjected—that its protective power has very considerably diminished, it is not unreasonable to suppose that the indefinitely greater number of transmissions to which variolous virus is subjected during the course of a world-wide epidemic may at length evolve a substance whose gradually diminishing energy shall finally become insufficient to infect those with whom it is brought in contact.

The manner in which this gradual attenuation may be effected is suggested by the experiments of Pasteur, Buechner, Greenfield, and others. These observers found that, by cultivation of the bacteria which exist in the blood of animals suffering with anthrax, these organisms might be made to vary their virulence to any extent. The harmless hay-bacillus can be thus transformed into a source of virulent poison; while, conversely, the anthrax bacillus can be entirely deprived of its dangerous properties. In like manner the fungus which yields the alcoholic ferment may be propagated in such a way as to produce no change of sugar into alcohol. The properties of the excreta of these lowly organisms depend entirely upon the manner in which their nutrition is effected. Now it is obviously impossible to trace the processes of nutrition in animal cells detached from the living body; but the points of resemblance between all cellular organisms are so numerous that we may with advantage use such observations as the above for the purpose of aiding our comprehension of the processes by which the once healthy substance of the animal body may be made to yield a virulent poison. Just as by a particular method of feeding we may transform a generation of harmless bacteria into a virulent source of poison, so it is probable that through certain variations in the nutrition of animal tissues they become the source of specific poisons, which are as uniform in their character as the tissues from which they are derived.

It is in this connection worthy of note that the hypothesis of the immutability of disease-poisons is inconsistent with the hypothesis of evolution. Such a belief is a survival from the crudest form of the creation hypothesis—assuming the origin, at some indefinitely remote period, of a disease-germ, which has ever since continued to reproduce itself without change. For such an hypothesis there is not one particle of proof, and yet it is the corner-stone of the edifice of modern sanitary science, so called.

The foregoing view of the subject enables us to dispense with the necessity for demanding a specific seed-germ as the cause of every infective disease. It also explains the origin *de novo* of the various infective diseases. It does not exclude the participation of diseased bacteria as vehicles and active agents in the multiplication and propagation of certain diseases, like diphtheria and anthrax. It helps to explain the variable intensity of what is vaguely called "epidemic influence." It further enables us to understand how it can be possible for diseases like syphilis to utterly disappear among long isolated populations like the former Pacific islanders, while they yet persist among continental races. But this is a subject too large to delay my pen at present.

To this doctrine of the variable energy of disease-poisons, the mere fact that communicable diseases do undoubtedly spread by contagion or infection forms no objection. But, if dependent for their continuous existence upon this cause alone, they should long since have disappeared from the face of the earth, just as small-pox disappears from the United States, or as measles disappears from Japan, after every epidemic visitation. Knowing what we do regarding the manner in which such forms of virus may undoubtedly vary, and observing as we do the manner in which they issue forth at certain epochs from certain regions of the earth, it is impossible to resist the conclusion that the persistence of these diseases is owing to the fact that they are continually recruited by fresh generation *de novo* (a very different thing, by the way, from *spontaneous generation*, as Dr. Chaillé very well knows) in certain definite territorial centres of origin. We know the original foci of cholera, of small-pox, the plague, and typhus fever, in India, China, Central Asia, and Great Britain. Were it not for the continued existence of conditions which develop those diseases, there is no reason why they should not have died out at their sources as well as in other countries to which they are from time to time conveyed.

To this doctrine, furthermore, it cannot be objected that the origin *de novo* of infective diseases is inadmissible because of the difficulty of excluding the possibility of infection in any given case. We already possess a number of well-authenticated cases of such origin. Witness the cases of phlegmonous erysipelas and of mumps originating on shipboard, under the eyes of Prof. Huxley, as recorded in Carpenter's "Physiology" (Eighth Eng. Ed., p. 291). Witness the similar naval origin of typhus fever, as recorded by Léon Colin ("Traité des Malad. Epidém.," p. 637). Witness the origin of typhoid fever on shipboard or on isolated islands, as related in recent numbers of *The British Medical Journal* (November 6, 1880, p. 740 *et loc. al.*). Witness the origin of "false diphtheria," as observed by McClellan, in Northern Idaho (THE MEDICAL RECORD, February 5, 1881, p. 163). The similar origin of genuine diphtheria is an occurrence too frequent for special mention (M. W. Taylor: *Brit. Med. Jour.*, p. 7, July 2, 1881). I am perfectly familiar with the arguments by means of which it is sought to parry the force of such illustrations. They will not bear analysis. What is thus true of so many of the infective diseases is probably true of them all. Some of them, like cholera, have comparatively limited territorial foci of origin, while others, like typhoid fever, may spring up in any quarter of the globe.

What now is the bearing of this discussion upon sanitary administration? The answer is this: Since infective diseases are continually originating as the product of man and his environment, it is useless to hope that they can be "stamped out" by isolation, disinfection, and so forth, in those countries where they are really endemic. Quarantine against yellow fever is very useful at New York, but it is of exceedingly little value at Vera Cruz. Isolation of scarlet fever may be very effectual at Key West, but is useless in Brooklyn. To attempt the suppression of measles and scarlet fever in our northern cities by simple isolation, etc., is merely touching the leaves of the tree without going to the root of the matter; just as the frightful quarantines of the middle ages never prevented the spread of the plague, until the

advance of civilization and the increase of wealth had completely changed the social condition of the people. This is a point which Dr. Chaillé seems to have missed altogether. He has sketched a very lurid picture of our ancestors in their hovels, two or three hundred years ago; and he would have us infer that our improved condition is the result of the labors of the hierarchy which he represents. But he has neglected to record the fact that from remote antiquity the population of Europe was harassed in vain by sanitary officials, until the world grew tired of them; and, shortly after the time of the Reformation, swept the whole brood into oblivion, where they did, for the most part, remain until about half a century ago. Great progress was made by mankind during the period of its emancipation. The death rate fell to one-half of its original figures; but since the revival of sanitary officialism it has remained nearly or quite stationary. Many things are yet in need of improvement, but this can only be secured by the progress of science and the diffusion of wealth. We have learned how to prevent typhoid-fever by the use of pure water, etc.; and now we need to discover a similar radical antidote for the miasmatic causes and nutritive perversions which originate and sustain the supply of measles, scarlet-fever, and diphtheria.

But if, in the meantime, while waiting for such knowledge, the prevalence of these domestic pestilences seems to be largely dependent upon conditions of contagion, like those which occasion the spread of small-pox, then we need to take a hint from our management of small-pox. We should seek to attenuate the virus of these diseases, so that we may protect ourselves against their malignant forms by experiencing their milder modifications. If this cannot yet be done, we should take another hint from the experience of mankind before the days of inoculation and vaccination. In those days the best thing that one could desire regarding small-pox was to have had the disease. So, at the present time, the best thing for any one, regarding measles and scarlet-fever, is to have had them both. The child who has experienced these diseases in early life, under the care of his parents, is far better qualified for an active part in the duties of life than the timorous victim of coddling isolation, who reaches manhood without security against unexpected and unavoidable exposure to an attack of measles or scarlet-fever at a time when his occupation and his social position may render such an illness disastrous.

(To be continued.)

Some Curious Pathological Conditions.—In the notes on autopsies, made at the Columbia Veterinary College, and published in the *Journal of Comparative Medicine*, there are some curious pathological conditions described.

In the case of a *swan*, the viscera were all healthy, except the large intestine. This was lined with a thick concretion, forming a solid pipe with a roughened interior.

In the pelvic cellular tissue of a *doe*, there was a bloody infiltration, giving the character of a pelvic hæmatocele. The uterus was somewhat enlarged, and in its right horn a well-preserved product of conception about eight weeks old was observed.

A very striking and typical picture of hæmorrhagic spinal meningitis was found in the case of a monkey (*cebus hypolemus*).

The examinations were made by Dr. E. C. Wendt.

## THE TREATMENT OF NASAL POLYPI BY INJECTION.*

By DUDLEY S. REYNOLDS, M.D.,

LOUISVILLE, KY.

CHAIRMAN OF THE SECTION ON OPHTHALMOLOGY, OTOLOGY, AND LARYNGOLOGY.

Nasal polypi have been regarded as amongst the most rebellious of all morbid growths, not excepting even medullary sarcoma; and there are many eminent writers who to this day maintain that nasal polypi are absolutely incurable—that they may not, by any means, be so thoroughly destroyed as to prevent their recurrence. It is needless for me to say that the best efforts of the most brilliant inventive genius in our profession have been directed to the destruction and removal of these pestiferous bodies. The galvano-cautery has been tried in vain, and various forms of forceps, snares, and ecraseurs have been introduced to professional notice from time to time.

Now, whilst I lay no claims to originality in the introduction of the practice which has been most successful in my experience, I imagine the method of procedure, however well known the means may be, has received insufficient attention in attempts to meet the demands of every detail. Polyps grow in abnormally warm and moist situations only. Polyps in the nose generally spring from the folds of mucous membrane, and are produced by long-continued swelling and infiltration of the roof of the naso-pharyngeal space—or from the crypts on each side of the superior turbinated bones, and in rare instances from situations along the septum narium, or between the inferior turbinated bones and the alæ, or between the middle and inferior turbinated bones; the rule being that they proceed from the walls and cavities which have been so long involved in a low grade of inflammation and so long closed by contact between opposite walls of small crypts or narrow spaces. It is manifestly impossible, without great violence to neighboring structures, to introduce any kind of crushing instruments or forceps, and at the same time separate the blades sufficiently to enable the surgeon to grasp the polypus or other morbid substance, however slender the pedicle may be. It is equally difficult to surround the pedicle of a polypus growing from a narrow crypt in the nose with any kind of galvano-caustic wire. The same objection applies to the various forms of canulæ, of snares, and even of the ingeniously devised and skilfully constructed ecraseur made so popular by my gifted young friend, Dr. Jarvis, of New York. After a long and very unsatisfactory experience in various methods of dealing with polypi in different situations in the nasal cavities, I have concluded that caustics properly applied to the pedicles of polypoid growths, or even to their bodies, might work the process of destruction more effectively and with less damage to contiguous structures than any of the various methods hitherto advised for the removal of such growths. Five or six years ago I began the practice of rolling a very minute portion of cotton-wool upon the end of a very small probe, dipping it into pure chloride of zinc, and thrusting it through the most accessible portions of the polypoid growths in the nose. Repeating this process at the end of four or five days, I rarely failed to secure death and sloughing of all the morbid tissues.

* An address delivered before the American Medical Association.

I then persisted in my efforts to resolve the remaining inflammation of the Schneiderian membrane throughout its extent, and had the satisfaction of seeing what appeared for a long time to be permanent immunity from a disposition to return of the polypi.

I finally noticed in the periodical literature of the day an account of some gentleman's successful treatment of nasal polypi with injections of strong acetic acid diluted with an equal bulk of distilled water. I had a solution of muriate of ammonia and bichloride of mercury compounded of two scruples of corrosive sublimate dissolved in half an ounce of a saturated solution of muriate of ammonia. Having a patient with a very ugly myxomatous polypus growing from the septum of the nose, and having but a few days before witnessed what appeared to me a very grave operation for the removal of just about such a growth from the nose of a patient of my friend, Professor Coomes, I decided to try a more powerful agent than the solution of corrosive sublimate above-named. Therefore I loaded a hypodermic syringe with pure chloride of zinc liquefied by exposure to the air, thrust the needle as nearly into the centre of the polypus and as well down toward the base as it was possible under the circumstances. I injected about three minims of the caustic. The patient suffered intense pain—so much, indeed, that I felt obliged to administer morphia to ease his sufferings. At the end of twenty-four hours, my patient, who was a robust farmer of about forty-five years of age, had become very nervous and depressed in spirits, and declared he was greatly damaged by the treatment, that he was getting worse every hour, and was quite discouraged. Examination of the nose showed a yellowish, sphacelated mass of substance distending the cavity of that side, accompanied by a great deal of engorgement of the contiguous surrounding structures. The opposite side of the nose, being by nature much narrower on account of deflection of the vomer toward that side, became entirely closed from the swelling in the Schneiderian membrane. The dejected spirits of the patient caused me to make an effort to rid him of at least a part of the obstructing matters of the opposite side. I took hold of the dead tissue with my forceps, pinching it upon the surface, and to my surprise and great gratification the polyp came away *en masse*, leaving the nostril entirely unobstructed. There was very free hemorrhage for a few moments—in fact, it was quite alarming for about five minutes. I rolled a little cotton-wool upon the end of a probe, dipped it in chromic acid and thrust it hard against the bleeding pedicle, the exact length of which could not be definitely determined at the time. In a few minutes the hemorrhage ceased, and by removing the clots which had already formed by pushing plugs of cotton-wool through, allowing the air in this way to be almost constantly in contact with the cauterized pedicle, the surface soon became glazed, and the man went out of the office greatly encouraged. Five days after the injection of the polypus Mr. M—— returned to his home in Ohio entirely relieved. Since that time he has been using occasionally finely powdered white sugar and tannic acid in the proportion of half a drachm of the tannic acid to the ounce of sugar. I hear from him occasionally, and am able to state that he has been entirely free from any nasal obstruction for more than eight months.

Mr. W. O. C——, principal of one of the ward schools in Louisville, had a series of polypoid growths springing from the crypts between the superior turbinated bones on both sides of the vomer. For many years Mr. C—— had suffered almost complete closure of both nares. The gradual enlargement of these morbid growths created an amount of distention of the nasal cavities which had become quite painful. The eyes were almost constantly filled with water, and, for the relief of the stillicidium lachrymarium, Mr. C—— was induced to seek my aid. A little examination satisfied me there was no obstruction of the tear-passages. Further investigation disclosed the state of the nasal passages already alluded to, both sides being completely plugged. I began by injections of pure carbolic acid, of from one to two minims, into the substance of the polyps on both sides of the nose, taking one to-day and another to-morrow. Within less than two months a series of polypi of enormous size had been destroyed in both nostrils, and the passages rendered quite free. The remaining rhinitis had been carefully watched and subdued, and Mr. C—— was, on March 20, 1881, discharged from further treatment, and requested to report weekly to the office, to enable me to make observation of his progress. Now, nearly two months having elapsed, and finding no disposition to a return of the growths, the rhinitis being entirely gone, I consider Mr. C—— permanently cured.

Miss M. F——, a young lady attending a fashionable boarding-school in Louisville, had long suffered from nasal polypi. Injecting one in the left nostril, aiming to introduce one minim of the pure undiluted liquefied carbolic acid, created so much pain, the suffering being so prolonged, that, notwithstanding the first polypus injected shrivelled and disappeared within a few days, I injected those remaining with the common officinal tincture of iodine, introducing from one to three minims at a time, according to their size. I had the satisfaction of seeing prompt disappearance by shrinkage of the polypoid growths, the pain, which has never been so great as that produced by the carbolic acid, lasting only for an hour or two. Three growths upon the left side and two on the right were destroyed in this way. Miss F—— has been almost entirely well for three months. As there is now no remaining rhinitis, and the passages are entirely free from obstruction, I conclude that she is permanently cured.

Miss J——, a young lady, of nineteen years, who had been obliged to quit school on account of the disgusting odor of her breath and the great difficulty she experienced in breathing at night, sought my services. An examination disclosed an entire absence of the inferior turbinated bones. A series of post-nasal polypi were removed, after which a very large growth of the myxomatous type was observed hanging from the crypt external to the superior turbinated bone. This was removed with forceps as nearly as possible, though a portion of the pedicle, as usual, remained.

Miss J—— appeared to recover, and was dismissed as being practically cured. Three weeks later she had an attack of intermittent fever, and returned with a series of polypoid growths in the left nostril, developed apparently from the remaining shreds of the primary growths, which had been removed from the crypt external to the superior turbinated bone. Believing further attempts with forceps unjustifiable, I practised the thrusting of the probe containing chloride of zinc up into the pedicle, and succeeded in this way in producing an amount of pain and inflammation decidedly distressing and alarming. As soon as this local discomfort had abated sufficiently to permit, I injected pure carbolic acid

with no apparent benefit. The vascularity of the pedicle being great, and the disposition to return being so decided and persistent, I concluded to inject the solution of corrosive sublimate and muriate of ammonia, already alluded to. This injection was followed by sloughing of the anterior growth of morbid substances, and speedy recovery, which has for a number of months remained, to all intents and purposes, perfect. I may remark in passing that I have tried pure commercial acetic acid. I have tried it diluted; I have tried the saturated solution of corrosive sublimate in alcohol, and all the other substances already named, and I have arrived at the conclusion that mucoid polyps are best relieved by carbolic acid injections; that the recurrent polyps with fibrous pedicle which may have resisted attempts at removal with forceps, or the action of the galvano-cautery, may, as a general thing, be best removed by injecting either the officinal tincture of iodine or the corrosive sublimate mixture. The myxomatous type of polypus may be removed with chloride of zinc, or a strong solution of corrosive sublimate and muriate of ammonia. The so-called hypertrophied tissue, or redundant mucous membrane covering the turbinated bones, can be made to shrink promptly and efficiently by the injection of the officinal tincture of iodine, which leaves no mark behind, and is attended by but little pain, and this always of temporary duration.

No matter what method is practised, after-treatment is of more importance than the removal of the polypus itself; because, unless the rhinitis which always attends the presence of polypoid growths of the nose—and which never ceases by their mere removal—is controlled, it will undoubtedly furnish all the conditions necessary for the reproduction of the growths. A very large number of cases might be cited in support of the principles already detailed, but it is believed enough has been said to indicate the importance of after-treatment, which should be conducted upon precisely the same plan as that pursued in obstinate cases of rhinitis unattended by polypoid growths.

## REPORT OF TWO CASES OF TRACHEOTOMY, WITH REMARKS.

By C. G. JENNINGS, M.D.

LECTURER ON CHEMISTRY AND DISEASES OF CHILDREN, DETROIT MEDICAL COLLEGE.

CASE I.—*Diphtheritic Croup.* A. K——, aged two years and three months, was first taken ill January 4, 1881. He complained of sore throat, was feverish and fretful, and coughed considerable. I first saw the patient on the evening of January 10. Examination showed the pharynx and tonsils covered with diphtheritic exudation, and the cervical glands swollen and tender. Temperature, 100°; pulse accelerated, but strong. The characteristic symptoms of laryngeal stenosis indicated the invasion of the larynx by the false membrane.

On the morning of the 12th, the severity of the dyspnœa became alarming. The cyanosis, feeble and rapid pulse, and failing strength, indicated a speedy fatal termination. Milder measures having failed, tracheotomy was proposed, as offering the only chance of life. At 12 M., assisted by Dr. Albert Campan, with the patient under chloroform, I opened the trachea below the thyroid isthmus. There was slight hemorrhage from one incised vessel; it was tied. After the insertion of the tube, artificial respiration was necessary, and had to be repeated at intervals for some time. Pulse was imperceptible at the wrist. Small doses of brandy and milk were administered every fifteen minutes. When reaction had taken place, the irritation of the canula caused incessant coughing. One-thirtieth of a grain of sulphate of morphia was given, with excellent results.

The room was kept at a temperature of about 80° F., and a constant evolution of steam maintained.

8 P.M.—Many pieces of membrane have been coughed through the tube. Temperature, 103°; pulse, 160; respiration very rapid. No signs of pulmonary inflammation. Ordered the brandy and milk continued; also ten grains of quinine, in two doses, per rectum.

January 13th, 9 A.M.—Had a bad night. The attendant had great difficulty in keeping the tube clear. Temperature, 101.5°; pulse, over 180. Two grains of sulphate of quinia were given every three hours; stimulants continued.

9 P.M.—Is much better this evening; sleeps well and takes plenty of nourishment. Temperature, 99.5°; pulse, 140.

January 14th., P.M.—Temperature, 100.5°; pulse, 160 Removed the canula, and found the wound inflamed, and covered with slight diphtheritic membrane. Dressed it with carbolized vaseline and absorbent cotton.

January 18th.—The wound has cleaned off, and looks well. Temperature normal; pulse, 120; pharynx clear of diphtheritic exudation; appetite excellent.

January 25th.—Patient is doing finely. He plays around as natural as ever. Sufficient air now passes through the larynx to admit of speech; occlusion of the tube, however, is followed in a few minutes by great distress. Another member of the family was taken yesterday with pharyngeal diphtheria.

February 4th.—The stenosis of the larynx has been rapidly disappearing, and now respiration can be carried on with perfect freedom for a little time with the orifice of the canula closed with a cork. Yesterday the removal of the canula to clean it was followed by dyspnœa so severe as to compel me to immediately replace it. Each subsequent attempt produced the same effect. To-day a second tube was inserted, while the other was being cleaned. Careful examination of the wound with reflected light failed to reveal the presence of fungous granulations, or anything that would account for the dyspnœa. A laryngoscopic examination could not be made.

February 12th.—The above condition continued for four or five days; since then no trouble has been experienced while cleaning the tube. The case, however, now presents the following unusual phenomena: In the morning, when the child is dressed, the mother closes the orifice of the canula with a cork—respiration is carried on without the least discomfort. When I make my visit, about eleven A.M., I remove the canula, and insert a solid wooden plug of the same size and shape, but not long enough to extend into the trachea. Now, so long as the child sits up and is tranquil, no difficulty is experienced; when, however, a deep, sudden inspiration is taken, either voluntarily, or in crying or laughing, an attack of dyspnœa supervenes, which necessitates the immediate replacement of the canula—*although the tube is still corked up, and no air can pass through it, relief is immediate.* A similar effect is produced when the child lies down, the difference being that

in the latter case the dyspnœa is gradual in its onset, and respiration *cannot* be carried on with the orifice of the canula occluded. The mother removes the cork when the child goes to bed at night or lies down during the day.

Such phenomena cannot be accounted for by any morbid condition of the larynx; the cause evidently must be a temporary change in the calibre of the trachea below the artificial opening.

The conditions following a tracheotomy on a young child are peculiarly adapted to bring about such a result. The trachea at that age is very soft and compressible, and is still further weakened by the opening made in it; it is also deprived of the support of the superjacent tissue.

For the first two or three weeks following the operation, the inflammatory induration surrounding the wound is quite sufficient to retain the anterior wall of the trachea in its place; later, when this induration has subsided, and before the formation of cicatricial tissue, a sudden deep inspiration, or even the recumbent position may cause it to collapse. The collapsed trachea would then act as a valve, partially or entirely preventing the entrance of air into the lungs.

The relief afforded by the insertion of the canula is readily explained. The shape of the tube and its position when in situ, are such that its anterior concave aspect forms a support for the lower edge of the tracheal wound.

March 4th (fifty-three days after the operation).—The boy's condition continued about the same as last recorded up to the beginning of last week. Since then such improvement has taken place, that the tube can be left corked up or removed during the whole twenty-four hours.

Yesterday he caught cold, and a general bronchitis has developed. I removed the tube and gave orders not to replace it unless absolutely necessary.

No inconvenience was experienced after this. The bronchitis responded readily to treatment, and the wound closed March 10th.

Case II.—*Membranous Croup.*—On the evening of May 5th, I was called to see F. V——, aged five years and seven months, previously a strong, healthy girl. She had been sick a week with symptoms of laryngeal inflammation. When I saw her she had all the symptoms of pseudo-membranous laryngitis in the second stage.

May 6th.—Notwithstanding the continuous use of the steam atomizer, and the free administration of emetics, the laryngeal stenosis had so far advanced that tracheotomy appeared to be the only means of prolonging life. I called in Dr. Albert Campan for advice and assistance, and at eleven o'clock, with the patient under chloroform, I opened the trachea below the thyroid isthmus. One of the veins of the thyroid plexus was incised and caused some trouble, but the bleeding ceased with the introduction of the canula. The patient rallied well after the operation, and in a short time passed off into a quiet sleep. The room was kept at a moderately warm temperature; and several folds of gauze were kept over the opening of the canula. 8 o'clock P.M.—Is bright and cheerful. Temperature 99.75°; pulse 140.

May 7th.—Passed a very quiet night. After quite a struggle this morning, a tough piece of membrane about two inches long, and large enough to almost entirely fill the trachea, was extracted through the wound. After this the air passed readily through the larynx. It closed up again, however, in about an hour. Temperature, 102.5°; pulse, 150. Ordered one grain of sulphate of quinia every two hours.

The case went on from this time with no untoward symptoms. The fever soon subsided, the larynx became patent on May 11th, and on May 16th, ten days after the operation, the tube was permanently removed. The wound cicatrized ten days later. For eight days following the removal of the tube there was complete aphonia, probably due to inflammatory thickening of the vocal cords.

The points of interest in the first case are the prolonged retention of the canula, and the causes which made it necessary. From the foregoing, the cause of the asphyxia when the tube was removed was evidently a collapse of the anterior wall of the trachea below the wound. Although phenomena similar to those above cited have been of not infrequent occurrence, as shown by the records of operators, this cause for their manifestation has been almost entirely overlooked. Dr. Cohen,* in his exhaustive monograph on tracheotomy, does not mention it among "the causes which prevent the early removal of the canula." Under the head of "spasm," however, he mentions several similar cases. In Protessor Steiner's report† of fifty-two tracheotomies, is recorded one case presenting analogous symptoms. The permanent removal of the canula was delayed about two years. At first the symptoms were ascribed to laryngeal spasm; but later this explanation was rejected, and the author acknowledged himself unable to assign a cause for the peculiar symptoms.

Dr. G. W. Rachel,‡ of New York, reports a similar case and offers a similar explanation. He is the only writer I know of who ascribes the symptoms to a change in the lumen of the trachea. In addition to the softness and pliability of the trachea, he considers the cervical curve of the vertebral column, which is more marked in children than adults, to be an important factor in the production of the dyspnœa.

The second case has nothing of particular interest, and only deserves a place in statistics. Together with the first it may help to give encouragement to an operation which, in some quarters, is still looked upon with suspicion; and this in spite of a fair proportion of recoveries, and the terrible mortality rate of the disease which demands its performance.

---

The Typhoid Fever Cases at Rugby, Tenn.—Dr. James T. Whittaker gives a report, in the *Cincinnati Lancet and Clinic*, of the epidemic of typhoid fever which broke out not long ago in the English colony at Rugby, Tenn. He found in all twenty cases among the four hundred inhabitants of the village. The cause of the disease seemed without doubt to proceed from drinking the water that had stood in an old cistern and had there become filthy; or, in other cases, from drinking the water from a shallow well that stood not far from the cistern. The cause of the infection was speedily abolished, and it is expected that there will be no more trouble.

The Insane Asylum at Binghamton, N. Y., has been placed in charge of a homœopath, Dr. Armstrong.

## THE MEDICAL USE OF STATICAL ELECTRICITY.

By GEORGE M. BEARD, A.M., M.D.

(Read before the American Neurological Association, June, 1881.)

Of the three forms of electricity—faradism, galvanism, and franklinism—the latter, franklinism, was first to be used, and is now again coming into use. For one hundred and fifty years franklinism has been used in medicine, and claims of a most stupendous character have been made for it as a therapeutic agent. Franklinism has a history of tremendous promise and tremendous disappointment. It was expected one hundred and fifty years ago, and was then claimed, and has been claimed during the last century and a half and during the last few months, in Europe and this country, that franklinism is superior, as a means of cure of disease, to galvanism or faradism. It is quite possible that it may have some advantages, in some diseases or for some temperaments, over galvanism and Faradism. But up to the present time there has been no proof of any such advantage offered by any of those who have written on the subject. It is possible—indeed, it is quite probable—and it seems to me, in fact, more than probable, that there are certain diseases, or at least certain temperaments, for which statical electricity, used in the form of sparks, or of insulation, or of shocks, or by the secondary statical current, or by all combined, will be of more service than the ordinary forms of galvanism and faradism with which we are all familiar; and I have hopes that in the future this will be demonstrated. During the past year I have myself been using statical electricity, more or less, every day, and am trying as best I can to answer that question. The reason that this question has not been sooner answered is, that we have had no machine that would go at all seasons of the year—no machine on which we could depend. That objection is now done away with. In Paris, Vigoroux has been using a modification of the Holtz machine, which is enclosed in a glass case, so as to keep out the atmospheric moisture, and is run by a small gas-engine. Inside the glass receiver is sulphate of lime, to absorb the moisture. Dr. Morton has described this machine. Mr. Berge, of this city, has lately constructed for me a machine which goes at certain seasons of the year —even in the early summer. It is, like all modern statical machines, a modification of the Holtz machine—the leading features being the use of gold tinsel, instead of points of charge, and four glass cylinders instead of merely two. It is run by boy-power, but a small glass engine would answer very well if any one thought it necessary. It gives all the current force needed, even during the last month, which we know has been unusually damp.

I am well convinced, from experiments this summer, that this statical machine of Mr. Berge will not answer for damp weather, unless it is enclosed in a glass case, as is done with the machines in Paris. My apparatus without a glass case worked very well indeed during the months of May and June, but in July, when the weather was excessively moist and warm, it stopped altogether or worked capriciously. It is impossible to use statical electricity in practice successfully, unless we have an apparatus that will go at all seasons of the year—summer as well as winter; for it is very annoying to begin treatment with a case, and then be compelled to suspend it because the machine will not work. We have been through these same difficulties in our early experiments with Faraday electricity and galvanic electricity. At one time it seemed that we never could get a good Faraday battery or a good galvanic battery—that is, one that would be good, neat, economical, and at all times trustworthy; but that difficulty has vanished long ago, and I am in hopes that, with the aid of the instrument-makers, we shall be able to get rid of all the practical difficulties that are now in the way of the use of statical electricity, at least among specialists. It is doubtful whether it can ever be used among general practitioners, or whether it can be carried about as conveniently as Faraday or galvanic batteries; but in this age we run great risks as to what may or may not happen in science and in invention.

Statical electricity acts both directly and reflexly, like other forms of electricity. It causes muscular contractions if used strong enough and condensed enough, just as other forms of electricity. It acts as an irritant, like other forms of electricity. The general philosophy of the sedative and tonic effects it produces is precisely like those of the other forms of electricity described in my writings on that subject. Ultimately analyzed, it is simply a molecular disturbance. The comparative value of franklinization, galvanization, and faradization, can only be estimated by those who are familiar with galvanization and central galvanization. Franklinization cannot be localized accurately—it must act upon the whole system; and any comparison between franklinization and the use of the other forms of electricity, in medicine, must be with their *general* Faradization and *central* galvanization, and not with local faradization and local galvanization. In Paris, Vigoroux told me that he obtained sedative and tonic effects from the use of statical electricity, but these effects have been obtained from the same form of electricity for one hundred and fifty years. Any published list of cases illustrating that is no addition to our scientific knowledge. To sum up in a word: the practical question before us in regard to statical electricity is not whether we can get sedative and tonic effects from it—that has been known for a century and a half—but whether its effects are superior in quality and quantity to those that can be obtained from central galvanization and general faradization, or from local use of galvanic and Faraday currents. That question can be answered only by those who are thoroughly familiar with general central and local methods of using electricity. We must have a standard of comparison, and a person who is not familiar with the general and central methods of electricity as they are used in this country and Germany, and have been for years, has no standard of comparison by which to judge of the comparative value of franklinization. The comparative investigation of this question is one of great difficulty. It is complicated with the general source of error of mind acting on body, and many other sources of error that cannot be mentioned here. My own conviction is that in time it will be proved that there are certain advantages for certain temperaments, possibly for certain diseases, but more likely for certain temperaments, in the franklinization; but this cannot be proved by any published list of cases where statical electricity has been used, unless the other forms of electricity in their general and central methods have been used in the same cases. Charcot or Vigoroux have no theoretical or practical knowledge of the use of electricity to medicine. They are not familiar with the literature of electro-

therapeutics—even in their own language—and all that they have thus far written on the use of statical electricity, save in regard to the form of machine, is more than a century old, both in science and experience.

It is needless to detail cases here, but this may be stated: that I have seen, during the past year, quite a number of cases of nervous diseases that have seemed to be more benefited by franklinization than by either galvanization or faradization. I make this general statement, taking into full consideration the sources of error to which I refer, and am open to all the correction that comes from larger experience of myself or others. The difference in the effects of franklinism and faradayism and galvanism is of degree, or not in quality; and it is very difficult, with a limited number of cases, to determine how great a degree of advantage there may be in franklinism in certain temperaments. One thing is established, and that is that delicate ladies will bear this treatment, and are not frightened by it, as it might be supposed they would be, when it is used carefully and without causing excessive pain. The sedative effects of the simple process of charging a patient is not comparable, according to my experience, with those obtained from galvanism or faradayism, when applied centrally or generally.

The convenience of not being obliged to remove clothing is, practically, not to be ignored, and in those cases where any current answers, will decide for franklinism.

We may have tertiary statical electricity by a third series of Leyden jars, if you wish; and I am having a set constructed for that purpose, more for the curiosity of the thing than in the expectation of using it any in practice. Indeed, the series might go on indefinitely, for all that I know, just as we have different coils of wires in the faradaic machines. In speaking of the faradaic battery, we use primary current for the current in the inner wire, and secondary for the current in the wire outside of it; and it would be in harmony with this nomenclature to call this current, from the first set of Leyden jars—the secondary statical current—statical electricity; and the current from the third set of jars, the tertiary.

The term "static induced," that Dr. Morton has applied to his current, has the disadvantage that it gives the impression that the phenomena of statical electricity, in general, are not induced, but that this current is induced *per se;* whereas, all the phenomena of statical electricity are the phenomena of induction.

The theory of the Leyden jars, from which this current is derived, is as follows: I take the description as found in the chapter on electro-physics, in "Beard & Rockwell's Medical and Surgical Electricity." "As the positive fluid collects on the inside, the outside becomes negative by the expulsion of the positive fluid naturally in it, and the accumulation of the negative fluid in its stead, drawn from the earth." The current, therefore, taken from the outside of the jars, is really a to and fro current, and can be regulated, as Dr. Morton says, by means of the movable rods connected with the prime conductors. Muscular contractions can be produced by this current, when used with a sponge, that resemble the contractions produced by the faraday current, and, as Dr. Morton says, far less painful than the primary statical electricity. It is, however, not much less painful than the faraday current from a battery like that of Kidder, or any battery of similar construction. I am now experimenting with this current. We shall all know more of it by and by. The nomenclature of all the forms of electricity used in medicine has always been an element of confusion, much more formerly than now. There were half a dozen terms, more or less, for faradism, and as many for galvanism. The primary current, the inner coil, was applied to the galvanic current oftentimes, even in good literature; so that, for a long time, it was impossible to tell what writers were writing about. Out of this confusion we have, in recent years, seized firm hold of these three terms: faradism, franklinism, galvanism, although a dozen or more synonyms are sometimes used.

As franklinism is now to be permanently used in medicine, it would be well to simplify the terminology by avoiding the superfluous word induction, and simply describe Dr. Morton's currents as secondary statical electricity, applying the term franklinism to all the phenomena of statical electricity.

I do not intend hereafter to abandon the electrical treatment of any obstinate case of nervous disease until statical electricity has been tried.

A single case illustrates my position on the subject. I was treating a lady with neurasthenia that had gone on to hysteroidal symptoms. She had hemianæsthesia. When she first sat down on the insulated stool, she could not feel the sparks of statical electricity that were on the right arm, but after an application of less than ten minutes she cried out "I can feel it now." Why did I not at once assume that franklinism had a specific power in the treatment of anæsthesia? Because I had seen other forms of electricity work rapid results in the same condition again and again, and because, also it is well known that symptoms of anæsthesia yield sometimes almost instantly to almost any influence that may be brought to bear upon it.

When Dr. Rockwell and I began the study of general statical electricity, we were astonished at the remarkable sedative and tonic effects produced. Those who are now using statical electricity or franklinism are astonished at the same effects. The effects with all forms of electricity are genuine and important and permanent; but a comparison of the relative quantity and degree of the effects of general and central application of the faradic and galvanic currents with franklinization is only possible to those who are familiar at least with the literature of electro-therapeutics.

---

Student-Life in Vienna.—Most of the American medical students are making a specialty of the eye, ear, and throat. The clinical material here is immense. The finest of all is the touch course, in the lying-in ward. It is worth a trip for that alone. In one course you have the opportunity of examining at least one hundred pregnant women, in all the different stages, and of applying the forceps and other manipulations, under the guidance of the Professor. There is nothing that can bear favorable comparison to it in America.

Excepting Paris, Vienna is the most expensive city in Europe. The climate is exceedingly changeable, demanding of one great discretion as regards clothing. Please allow me to correct a false impression that nearly all Americans possess regarding the cheapness of student-life in Europe. If a student attends all the courses he wishes and obtains comfortable board, it is not possible to spend less than one hundred dollars per month. This is even calculating very closely, for everything is very dear.—*Cor. of College and Clinical Record.*

# Reports of Hospitals.

## NEW YORK HOSPITAL, N. Y.

(Reported by GEORGE M. TUTTLE, M.D., House Physician.)

### DOUBLE LOBAR PNEUMONIA—EMPYEMA—OPERATION—CURE.

WHILE a successful issue to the operative treatment of empyema is by no means a rare event, a glance at the fruitful literature of the subject makes it evident that there is considerable diversity of opinion not only as to the individual methods employed, but also as to the fundamental principles to be observed.

The following case is offered simply for the reason that the perfectly successful result would seem to warrant its presentation.

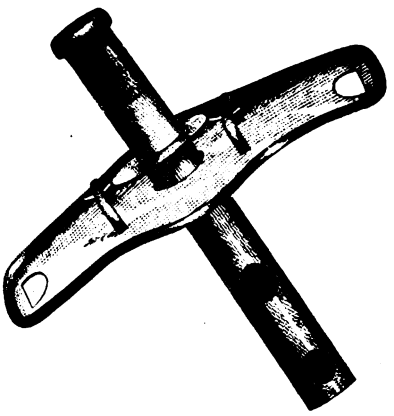
John W. B——, a colored waiter, twenty-two years of age, was admitted to the wards of the hospital on the 1st of last May, in the service of Dr. James W. McLane. He had been in good health up to April 26th, six days prior to admission, when exposure to cold and wet was followed by a well-marked chill, headache, severe pain in the right side, rapid, difficult breathing, and subsequently short, painful cough, with scanty, tenacious, rusty sputum. Temperature on admission, 102.6° F., and patient's condition one of marked prostration. Physical examination revealed an area of pulmonary consolidation on the right side from the spine of the scapula to its inferior angle, and extending in this plane around the axilla, and anteriorly, as manifested by a dull percussion note, exaggerated tactile fremitus, tubular breathing, with crepitant râles and loud, ringing bronchophonic voice. Over the same side of the chest, from the inferior angle of the scapula to the base of the lung, a flat percussion note, with loss of expansion, tactile fremitus and respiratory murmur, and a faintly conveyed bronchial voice, revealed the presence of fluid in the right pleural sac. There was no apparent bulging of the intercostal spaces. Sputa rusty. Urine contained a one-tenth bulk of albumen and many hyaline tube-casts.

For the week following admission the patient's temperature ranged between 101° and 102° F., the signs of consolidation becoming less and less intense with an occasional râle redux. On May 8th a small patch of consolidation was discovered in the left lung, in the interscapular region, the pneumonic process gradually involving the apex. By the 16th, resolution seemed complete in either lung, with the exception of rude respiration at the apices, but the patient's prostration became more profound, and he was observed to sweat profusely at night. The temperature still ranged from 99° to 102° F. A hypodermic needle was inserted just below the inferior angle of the right scapula, and a syringeful of thick, yellow, laudable pus withdrawn from the pleural sac. Renewed physical examination showed the fluid level to be two inches above the inferior angle of the scapula, while slight but well-marked bulging of the intercostal spaces was apparent.

Mensuration at nipple level: right chest, 16¼ inches; left chest, 15½ inches.

At the right apex, anteriorly, tubular breathing, with harsh vocal sounds, gave evidence of the crowding of the lung upward and against the spinal column. The upper border of the liver could not be defined; its lower border was one inch below the costal edge, in the mammary line. Position of the heart normal.

With the patient's full consent, operation was at once decided upon, and Mr. Ford, of Caswell, Hazard & Co., made for me the following instrument: a trocar carrying a simple, straight, thin silver canula, one-fourth of an inch in diameter, two and five-eighths inches long, with a very large, broad swivel-plate, placed at a distance of one and one-half inch from the inner end of the canula, the plate having free lateral motion. The inner end of the canula



was blunted to prevent any injury from its impinging upon the lung; the outer end was fitted with a small collar, to give firm attachment to a rubber tube closed by an air-tight nickel valve. Three smooth fenestra were made in the inner portion of the canula, and large holes in the swivel-plate for tapes to secure the whole apparatus. The instrument is nothing but a large modified tracheotomy-tube.

On May 21st the patient was etherized, and, under full antiseptic precautions, an incision was made with a bistoury in the ninth intercostal space—the lowest practicable point—in a line with the inferior angle of the scapula, and the trocar, carrying the canula, easily introduced into the pleural sac. The presence of pus at this point was tested by a hypodermic needle just before the incision was made. On withdrawing the trocar a full stream of pus poured from the canula, but none oozed from the pleural sac along its sides. The rubber tube with valve was now attached, and after allowing twenty ounces of pus to flow out, the valve was closed, the end of the rubber tube placed in a large wad of borated cotton, and the whole thorax enveloped in a broad Lister dressing, the edges of the latter being kept tightly coated to the chest by long rubber bandages.

At the time of operation, 3.20 P.M., the patient's temperature was 101.2° F. At 5.30 P.M. the temperature was 98.8°; and the patient free from pain or even discomfort. On the following day, May 23d, the temperature rose in the afternoon to 102.8°, but the patient had no pain, cough, or sweating. The dressing was removed under the spray, and found absolutely clean. Ten ounces of pus were allowed to flow out, great care being taken to prevent the ingress of air, and the dressing reapplied. The temperature immediately fell to normal. Examination now revealed a good, resonant percussion note, and rude vesicular breathing at the right apex, in place of former flatness and tubular breathing. During

the next five days the temperature did not rise beyond 99° F., from ten to twelve ounces of pus being withdrawn daily; the patient in the meantime being wholly free from cough or pain, and able to lie on either side, and to sit up while the dressings were changed. Examination showed good vesicular breathing and full, resonant percussion note anteriorly from the apex to the fifth rib, and posteriorly as low as the inferior angle of the scapula. A few friction râles were heard in the right mammary region.

June 5th.—On opening the valve no pus flowed, and it was observed that no air entered or issued through the canula. Passing through the latter a small, flexible catheter, complete canalization by recent granulations was found to have taken place about the canula. With slight force these were pushed aside, and pus flowed through the catheter. Some air having entered the chest, and no collapse of the lung following, it was decided to wash out the sac with a solution of thymol (1 to 1,000) and this was done in the usual manner, by means of a glass funnel and suitable tubes attached to the catheter, the latter being passed through the canula well up into the chest, and a very gentle stream allowed to flow in, returning at the same time through the canula by the sides of the catheter. This was done until the returning fluid was clear. The thymol solution was carefully kept at a temperature of 104° F.

June 23d.—Pleural sac washed out daily since last date. No pain or cough. Temperature frequently rises in P.M. to 101°, and on one occasion it reached 104° F., falling usually to normal after changing the dressing. One to two ounces of laudable pus are evacuated daily. All over the lung, anteriorly, a high-pitched percussion note, exaggerated fremitus, numerous friction râles, and more distinct vesicular breathing, give evidence of the thickening and union of the granulating surfaces of the parietal and visceral pleural.

June 30th.—Highest temperature during past week, 100.8°—usual, normal. Patient has gained six and a quarter pounds, and has been allowed to sit up for the past few days.

July 4th.—No pus obtained, and the thymol solution returned from the chest clear. Granulations about the canula effectively prevent the entrance of air into the pleural sac. Silver canula removed and Lister dressing discontinued. Patient now allowed about ward; has gained five and a half pounds since last date, and temperature is uniformly normal. No pain or cough.

July 10th.—Patient has gained twenty-two pounds; feels perfectly well, and is anxious to be discharged, but agrees to remain for a time under observation.

July 27th.—Patient insists that he is as well as he ever was, and says that he ran up-stairs "two steps at a time."

Examination shows a full, round, symmetrical thorax, with fine muscular development. Cyrtometer tracings at nipple level: right side, 16½ inches; left side, 16½ inches. At junction of last cartilage with sternum: right side, 15½ inches; left side, 15 inches. Expansion same on both sides. All over right chest, as compared with the left, the percussion note is dull and high-pitched; tactile fremitus exaggerated; breathing vesicular, but distant; voice distant and vibrant. Below the point of incision, from the great thickening and abundant granulations, both voice and respiratory sounds are distant but distinct, while the percussion note is very dull. Lower border of liver is at costal edge. Patient discharged cured.

A complete cure, keeping in mind the possibility of future complications, was secured in seven weeks from the time of operation, the patient having suffered a minimum of pain and discomfort, and having had but two small doses of morphine, and no stimulants. In the treatment of the case the following principles were carefully adhered to:

*First.*—The rigid exclusion of all air from the pleural sac until the crippled lung had had ample time to expand and contract adhesions.

*Second.*—The admission of no air that was not rendered thoroughly antiseptic.

*Third.*—Gradual withdrawal of pus from the pleural sac.

*Fourth.*—Free exit of fluid while washing out the chest, so as not to break up fresh adhesions between the two pleural surfaces.

The only advantages claimed for the canula, which is susceptible of various modifications and improvements, are simplicity, cleanliness, and ease of management, especially when washing out the chest.

Taking into consideration the known lack of recuperative power in the patient's race, his prostration after a double lobar pneumonia, the large amount of pus in the pleural sac, and the compression of the lung, the very gratifying result of the above treatment would seem, in a measure, to justify the strict adherence to the principles stated.

## Progress of Medical Science.

BORACIC ACID IN THE TREATMENT OF CATARRH OF THE BLADDER.—Rosenthal (*Wiener med. Blätter*, No. 46) recommends boracic acid very highly in the treatment of cystitis, whether of peripheral or central origin. He usually prescribes: ℞. Acid. boracic, 2 grammes; aquæ, 100 grammes, with the addition of syrup. aurantii cort., the whole to be taken in the course of a day. The mixture tastes like weak lemonade, and may be given for a long time without producing the unpleasant secondary effects of salicylate of soda, chlorate of potash, and the oleo-resins. In the more severe cases of cystitis with profuse secretion of mucus and pus, so-called cystitis ammoniacalis, Rosenthal also washes out the bladder twice a day with a five per cent. solution of the same agent.—*Allgem. med. Central-Zeitung*, No. 41, 1881.

TREATMENT OF CHRONIC URETHRITIS AND SPASM OF THE BLADDER.—During the past ten years, Weiser has adopted a new method of treatment in chronic gonorrhœa, and out of twenty-five cases he has succeeded in curing all but one patient. The latter was afterward advised to consult Dr. Grünfeld, who, by means of the endoscope, discovered granulations in the urethra, which, being cauterized, the man got well after several weeks' treatment. Weiser first passes an elastic or a metallic catheter into the bladder, and, after thoroughly evacuating the viscus, injects into it by means of a clysopompe, or, preferably, an irrigator, a solution of sulphate of zinc, 2.0 to 3.0, and tannin, 0.5, in 500.0 of water, at a temperature of 26° R. The catheter is then withdrawn, and the patient directed to empty his bladder, thus bringing the medicated solution in thorough contact with the whole of the urethra. This method

is effectual in all cases where no granulations exist. The latter require the application of caustics. The author has, however, omitted to state how long the treatment must be continued. In cases with associated cystitis, 3 to 4 drops of nitrite of amyl should be added to the above solution, the former being a very active disinfectant, 1 or 2 drops added to a bottle of urine serving to prevent the development of ammonia in the latter for a couple of years. When strictures are present, they should be treated with metallic sounds. For the relief of cystospasms, the above mentioned solution may also be employed; one or two injections a day, continued for an average period of three months, usually suffice to entirely cure this condition. Frictions with cold water and lukewarm (26° R.) sitz-baths may be employed as adjuvants.—*Mittheilungen d. Wiener med. Doctoren-Collegiums*, June 23, 1881.

Operative Cure of a Case of Hernia of the Umbilical Cord in a Girl of Sixteen Days.—At a recent meeting of the Medical Society of Vienna, Breuss exhibited a female infant, with the following history:

At birth, an umbilical hernia was noticed. Reduction having been accomplished without opening of the sac, the neck of the latter was compressed with small hæmostatic forceps, after which the sac, which was afterward found to contain recently inflamed peritoneum, was cut off, the stump ligatured, cauterized with a Paquelin thermo-cautery, and then covered with a Lister dressing. The operation was performed twenty hours after birth, and was well borne. On the eighth day, the pedicle being clean, the ligatures were removed, and now there is to be seen at the site of the hernia only a small, granulating stump, which is not even protruded when the infant cries or strains.—*Allgem. med. Centralzeitung*, June 22, 1881.

Pilocarpin in Uræmia following Scarlatina.—Preetorius reports (*Allgem. med. Centralzeitung*, June 25, 1881) eleven cases of uræmia after scarlatina, which were treated in the clinic of Prof. Kohts, at Strasburg, by injections of muriate of pilocarpin. Five of these patients were entirely cured, a sixth died five months later of diphtheria. These results must be regarded as very favorable, especially when we consider that in the five fatal cases severe complications were present, such as pneumonia, pericarditis, etc. To avoid collapse, Praetorius advises beginning with a small dose of the remedy, and injecting one-half milligramme five minutes later, if sufficient action have not manifested itself. Like Demme, the author concludes that pilocarpin is ineffectual in cases of extensive glomerulo-nephritis, and that it acts not only as a diaphoretic, but as a direct stimulant of the renal secretion.

Seeman, of Berlin (*Zeitschrift für klinische Medicin*, vol. ii., part 3), has treated nine cases of scarlatinal dropsy with pilocarpin, after other remedies had proved useless. Five cases got well, without intercurrent complications, after two or three injections of from 0.005 to 0.01 of the muriate; a sixth developed catarrhal pneumonia after the employment of the remedy, but recovered; in another case the injections were followed by uræmic convulsions, terminating favorably; another patient was twice attacked by bronchitis after the use of the pilocarpin; while the last case, one of scarlatina, with subsequent diphtheritis and nephritis, with enormous dropsical effusion, was attacked by pneumonic symptoms after the second injection, and the third injection was followed three days later by fatal pneumorrhagia.

The author seems inclined, in these cases, to consider *post hoc* equivalent to *propter hoc*, and for the following reasons: in the patient who was attacked by uræmic convulsions, the dropsical effusions probably contained (as has been shown in similar cases by Voit and others) considerable quantities of urea; the profuse diaphoresis incident to the employment of pilocarpin led to the rapid absorption of the dropsical fluid then overloading the blood with urea; hence the convulsions. As regards the three cases complicated with inflammation of the respiratory tract, it must be remembered that the employment of pilocarpin is immediately followed by "excitation of the nerve fibres, inhibiting the tonus of the peripheral vessels," that is, the peripheral vessels dilate, the current of blood slows up as a consequence of the lowered arterial pressure, so that the tissues are bathed in a superabundance of blood-serum. These conditions lead to increased secretion, sometimes also to stagnation of blood and disturbances of nutrition; in some cases even to rupture of the vessels, as has been observed by Ohms and G. Lewin.

Seeman, therefore, advises: 1st, that pilocarpin should be used only in obstinate cases of scarlatinal dropsy; 2d, that, when the favorable effects of the remedy have once manifested themselves, one should not endeavor to bring about a too rapid absorption of dropsical effusions, lest uræmic symptoms develop, but should allow nature to complete the cure; and, 3d, that whenever pilocarpin is employed, the condition of the respiratory organs should be carefully watched, and the drug should be set aside as soon as it is found that expectoration is not sufficiently energetic to expel the abundantly secreted mucus, or whenever the first symptoms of pneumonia are detected.

Thrombosis of the Inferior Vena Cava.—In the *Charité Annalen*, vol. vi., 1881, Henoch narrates a case of the above in which the symptoms were such as to enable the diagnosis to be made *intra vitam*. The patient, a boy of seven years, had a mild attack of scarlet fever in August, 1877, and had suffered ever since from diarrhœa, becoming greatly emaciated. During February of the present year, marked œdema of the inferior extremities, scrotum, and penis, set in. At the same time the superficial abdominal veins, particularly in the epigastric region, became greatly dilated. The urine was diminished in quantity, free from albumen, and microscopically normal. Physical examination of the chest and abdominal viscera disclosed nothing abnormal. The œdema became more intense and spread over the skin of the belly and lumbar regions, while the veins on the abdomen, and down as far as the dorsum of the foot, formed thick blue cords. Fever of a remittent type set in, and, on March 2d, death occurred. At the autopsy the vena cava inferior was found converted into a solid cord, the thrombus extending into the iliac veins, and from here into the peripheral veins. Numerous tubercular ulcers were found in the intestines.

The fact that the liver was not enlarged during life showed that there was no obstruction at the point of entrance of the hepatic veins into the inferior vena cava. The absence of any signs of passive renal congestion proved that the thrombotic process was very slow and gradual, allowing sufficient time for the establishment of collateral circulation be-

tween the veins of the renal capsule and the vena azygos. It was evidently a marantic thrombosis due to cardiac weakness, coagulation commencing in the lower extremities and gradually extending centrally. —*Allgem. med. Central Zeitung*, June 25, 1881.

ASCITES IN CHILDHOOD.—Seiler communicates the histories of four cases of ascites occurring in children between the ages of four and fifteen years, and characterized by the presence of a large amount of free, clear, sero-albuminous fluid in the peritoneal cavity, great enlargement of the liver, absence of pain and fever, and good general health. The affections during the course of which ascites develops may be classified under two heads, leaving out of consideration that form which is a concomitant of general dropsy, and such rare conditions as ascites chylosus and fatty degeneration of the peritoneum. 1st, Localized disease of the peritoneum; 2d, Interference with the circulation in the portal vein. Tubercular peritonitis belongs to the first class; it may occur in children, but the morbid process rarely remains confined to the peritoneum, and it is usually, if not always, associated with fever of an irregular type, with sudden and severe remissions, or with a subfebrile state lasting months. Sometimes, however, fever may be absent for several weeks or months, and tuberculosis of other organs may not be discoverable, but characteristic emaciation is always present, as well as some degree of abdominal tenderness. A second disease of this class is primary carcinoma of the peritoneum: it is characterized by hemorrhagic exudations of a cherry-red or dirty brown color. As regards chronic idiopathic peritonitis, Seiler is inclined to doubt its existence. To the second category belong first carcinoma and sarcoma of the liver; as far as the author knows, no instances of this disease have been met with in childhood. Syphilitic gummata cause ascites only when they are so situated as to compress the portal vein at its entrance into the transverse fissure. Birch-Hirschfeld, Virchow, and the author, have described such cases. The third and most important form of hepatic affections which produce ascites, is cirrhosis. It is very doubtful, however, whether genuine instances of this disease occur in childhood (Gerhardt: "Diseases of Children"). Cases described as such are probably of syphilitic origin. Taylor (*British Med. Journal*, January 5, 1880) believes that the cases collated by Wickham Legg (*St. Bartholomew's Hospital Reports*, 1877) are instances of late congenital syphilis. Simonds (*Archiv. fuer kl. Med.*, 1880) asserts that there is no anatomical difference between hepatitis syphilitica and cirrhosis. Clinically, the hypertrophic stage of cirrhosis of the liver is not distinguishable from diffuse syphilitic hepatitis so long as the only recognizable symptoms are ascites and enlargement of the liver. Seiler was thus led to infer that his above-described four cases belonged to the class of diffuse syphilitic hepatitis, and he treated them accordingly. He first drew off the fluid by tapping, and then prescribed inunctions of mercurial ointment with the internal administration of iodide of potassium and tonics. The results were excellent. Ascites did not recur, and the liver rapidly diminished in size until its dimensions were normal. Two of the patients were seen several years afterward, when they were found to be in perfect health; the other two disappeared from observation. The author finally arrives at the following conclusions: 1st, Ordinary ascites in children depends, whenever tuberculosis can be excluded, upon diffuse syphilitic or circumscribed gummy hepatitis, even when other signs of syphilis are absent. The cases that have hitherto been reported belong to the category of syphilis hereditaria tarda. 2d, The disease is always curable by mercury, iodine, or a combination of the two. The only other possibility is that there occurs in childhood a simple hypertrophic cirrhosis of the liver, which is susceptible of cure.—*Berliner klin. Wochenschrift*, June 27, 1881.

CASE OF RETRO-UTERINE HÆMATOCELE TREATED SUCCESSFULLY BY MASSAGE.—Succinctly stated, the patient was a woman, twenty-seven years old, about two months pregnant, who, after taking various drugs, resorted to an electric bath for the purpose of inducing abortion. A full current from sixty large Daniell's cells was used, one pole being placed on the sacrum, the other at or just within the vulva. The procedure was quite painful, and was followed by slight bloody discharges. A few days later, on March 13, the patient was seen by Dr. Rosenstein, who found an abortion in progress, and a very large retro-uterine hæmatocele. The former terminated after a day or two in expulsion of the ovum, while the latter attained an immense size owing to negligence on the part of the woman, who got up and walked about against advice. By May 2d the hæmatocele had become hard and immovable, and was as large as ever, filling out the iliac fossæ and abdomen as high as the umbilicus. Poultices, inunctions of iodoform, etc., had proved ineffectual. Rosenstein then resorted to massage, introducing two fingers of the left hand into the vagina and gently pressing against the swelling, while the right hand was employed in stroking and kneading the tumor from without. The sittings were given at first twice a day, afterward once a day, fifteen minutes at a time, and after the lapse of about six weeks the exudation had entirely disappeared, the uterus being freely movable. —*Centralblatt fuer Gynœkologie*, June 25, 1881.

THE ABSORPTIVE POWERS OF THE BLADDER AND URETHRA.—Maas and Punier have performed experiments on animals and men, which demonstrate conclusively that the bladder, whether healthy or diseased, as well as the urethra, possesses the faculty of absorption in a greater or less degree, varying with the substance used. Their methods when experimenting on animals were as follows: The bladder was fully exposed, both ureters tied about one ctm. above their termination, then divided above the ligatures and the urine conducted outside of the body by means of glass canulas introduced into the central ends. The bladder was then evacuated by a catheter, through which the solution experimented with was injected, the catheter withdrawn, and a ligature drawn tightly around the urethra between the prostate gland and the neck of the bladder; sometimes after tying ureters and urethra the bladder was emptied by a Pravaz syringe, the medicated solution injected through the canula of the latter, and the puncture closed by ligature. In a second series of experiments the abdominal cavity was not opened, but, after drawing off the urine, the solution was injected through the catheter, and the mouth of the latter plugged. The substances used were ferrocyanide of potassium, salicylate of soda, cyanide of potassium, strychnine, atropine, curare, apomorphia, and pilocarpin. All of these substances were absorbed, but some so slowly that their physiological action was not manifested; thus atropine seemed to have no effect upon the animal, but a small quantity of its urine collected during the continuance of

the experiment and instilled into the eye of another animal, rapidly caused dilatation of the pupil. The diseased bladder was also found capable of absorbing the same substances. In their experiments on man, Maas and Punier used iodide of potassium and pilocarpin. As regards the excretion of the former, they call attention to the fact that in some individuals it rapidly passes off by the urine, in others by the saliva, and in others by only one of these paths to the exclusion of the other. The method used was the following: Taking only individuals with healthy bladders, the latter were evacuated by a Nélaton catheter, after which in twenty-eight cases they injected fifty grammes of a ten per cent. solution of iodide of potassium, following this up in thirteen other cases with an injection of one or two centigrammes of muriate of pilocarpin half an hour later. The iodide was detected in the saliva in fifty-seven per cent. of the first, and seventy-seven per cent. of the second series, but usually in small quantities only. The diseased bladder was found to absorb much more promptly; iodide of potassium was detected in the saliva when only 2.0 were used. A solution of 0.04 morphine in 2.0 aq. destill. used in this way, acted very plainly as an anodyne. Pilocarpin made up into a bougie with cacao butter, and introduced into the urethra (both healthy and diseased), manifested its specific effects.—*Centralblatt fuer Chirurgie*, June 25, 1881.

Diaphragmatic Hernia.—Lacher has made a careful study of this subject, based upon two hundred and seventy-six cases collected from various sources, to which he adds three cases from his own practice. Following Cruveilhier, he recognizes two main divisions, congenital and acquired. Of the whole number only ten per cent. were true diaphragmatic herniæ, that is, were enclosed in a hernial sac. The left side was affected five times as often as the right. This is due, not as has been previously supposed, to the greater weakness of the left half of the diaphragm, but to the support given by the liver, the greater length and firmness of the right crus, as well as to the absence on the right side of such openings as the aortic and œsophageal foramina. The fleshy portions of the diaphragm offer less resistance to the escape of abdominal viscera than the tendinous parts. The weakest points are the interstices between the muscular bundles, the triangular space immediately behind the sternum (so-called Larrey's space for puncture of the pericardium), the foramina Bochdalecki—more patent on the left than on the right side—and the œsophageal foramen. No case is recorded of hernia through the foramina for the aorta and vena cava inferior. When the cause is traumatic, the margins of the hernial opening are torn and ragged; in other instances, especially when congenital, they are smooth and callous. With the exception of the genital apparatus, every one of the abdominal viscera has been found in the thoracic cavity, the stomach and colon naturally occupying the first rank. In congenital cases the ratio between males and females is about equal. The acquired variety is more common in males, probably because of their occupations and mode of life. No new etiological points are presented. As regards symptomatology, there is a wide difference between chronic and acute cases. The former very often remain latent, while the latter, when death does not occur immediately as the result of the injury, are characterized by violent pain in the epigastrium, intense dyspnœa and cyanosis from compression of the lung and displacement of the heart, unequal expansion of either half of the thorax, small and frequent pulse, nausea, vomiting, etc. If the symptoms have abated, they may again be occasioned by any increased tension of the intestinal tract following errors in diet, muscular exertion, etc. For these reasons the prognosis must always be dubious, even when the hernial opening is ample in size and the symptoms have been quiescent for years. In acute traumatic cases, Lacher imagines that laparotomy under antiseptic precautions may with propriety be performed.—*Centralblatt fuer Chirurgie*, July 2, 1881.

Alcohol: Its Therapeutical Uses Internally and Externally.—Bartholow's paper on this subject, read before the Philadelphia Medical Society, and published in the *Medical Times*, July 16, 1881, contains a number of interesting points. As a stomachic tonic, he says, alcohol is effective only in the case of those not habituated to its use. It should be given properly diluted, and administered immediately before meals, in order to stimulate digestion; for the action of alcohol as a stomachic tonic consists in the power it has to cause a prompt congestion of the mucous membrane, and the increased activity of the gastric glands is a necessary consequence. A catarrhal state of the mucous membrane is produced, and a pathological secretion obtained by long continued use. When alcohol is used to promote the nutrition in general, it should be administered during and after meals. The quantity should be sufficient to stimulate the gastric glands, and yet short of the strength necessary to precipitate the pepsin. The amount required in wasting diseases—as in chronic suppuration and in phthisis—will be more, and it will be better borne than in other chronic maladies of a depressing kind. The best results are derived from half an ounce to an ounce of whiskey or brandy, taken during or immediately after meals; for thus the stomachic tonic effects and the full value of alcohol as a food are obtained. Amylic alcohol has no specific action in consumption. In certain diseases of the digestive tract, alcohol in its various forms is highly useful. A tea- to a tablespoonful of raw brandy will sometimes check obstinate vomiting, not dependent on inflammation of the stomach. In the vomiting of uræmic intoxication, and especially of yellow fever, a dry champagne, or our native sparkling wine, may be very successful. A simple diarrhœa may be checked by brandy. In cholera infantum we have in brandy the most generally efficient curative agent. Infants bear a relatively larger quantity of alcoholic stimulants, but it is not known that large doses of brandy are singularly efficacious in this disease. Dr. Bartholow has given half a teaspoonful to a teaspoonful of cognac brandy every three hours to a child under one year, and above that, to three years, one to two teaspoonfuls. It should not be given in milk, but in water as warm as possible, and as remote from the time of food-taking as possible.

In the atonic dyspepsia of the sedentary and the feeble digestion of the convalescent, alcohol is useful in a high degree. A wine of good body and decided bouquet has been found very efficacious in the weak digestion of literary and nervous sedentary persons. In the case of a convalescent, a spirit is preferable to a wine. To the literary and nervous invalid class, the wine proposed is especially grateful, and they are responsive to a high degree. As the wine is to play the part of both stimulant to the digestive organs and a food for the nervous tissue,

the best results are had from a generous wineglassful taken during the principal meal. The kind of wine selected must be determined by several considerations. If the organs simply require stimulation, a good dry sherry or Burgundy may be best adapted to the case; if an excess of acid be present, due to the fermentation of the saccharine and starchy foods, a sweet wine is objectionable, but then an acid Rhein wine of high alcoholic strength—as, for example, the Förster Riesling—may be serviceable in a remarkable degree. For the weak digestion of convalescence, it is well known that a considerable quantity of spirit is borne well, and required. In both groups, but in an especial degree in the nervous and depressed invalid, the effect of alcoholic stimulation is peculiarly grateful and seductive: hence the danger of the alcoholic habit, and the need of circumspection in prescribing a remedy which may be so abused. It is a cardiac and arterial stimulant, acting first by reflex, *i.e.*, the diastolic interval is shortened by its influences; secondly, the power of alcohol to increase the rate of the heart's movement is explained by the fact that the oxidation force generated is utilized by the cardiac ganglia. Small doses stimulate the circulation, large doses have the opposite effect; therefore, to overcome cardiac depression the stimulant must be administered in small quantity, but frequently. In many cases, a wine of good body, highly charged with œnanthic and other ethers, is preferable to a spirit.

Referring to the practice adopted by Dr. Sands, of New York, of inducing alcoholic intoxication as a preparation for the administration of ether or chloroform to prevent shock, Dr. Bartholow regards it as good practice if the heart is sound and the full anæsthetic state is desired. He regards it highly improper to inject brandy or whiskey subcutaneously with a view to stimulate the respiratory and cardiac centres in chloroform or ether narcosis—indeed, it contributes to a fatal result.

The antipyretic effects of alcohol involve more doubtful questions than the therapeutical effects heretofore considered, but the weight of authority is unquestionably in favor of the view that alcohol in large doses depresses the temperature. In the treatment of acute inflammations and fevers we may employ alcohol as an antipyretic to depress the abnormal temperature, or as a support to the circulatory system and a stimulant to the digestive function. In the former case large, and in the latter small doses, are necessary. Alcohol does not compare with the cold bath, with quinine, even with digitalis, as an antipyretic. It does good when the tongue changes from dry to moist, when the stomach can receive and digest more food, when the pulse declines in rapidity and gains in force, when the surface grows moist and cool from hot and dry, when the delirium ceases and an expression of intelligence replaces blank stupor. Alcohol as an antiseptic is well known to be effective in the septic maladies; it must be administered in large doses. There must be maintained, in a certain sense, a saturation of the blood to act on the materies morbi efficiently.

The power of alcohol to coagulate albumen, to suspend the activity of the unorganized ferments, and to destroy minute organisms, lies at the foundation of its external uses. It is a most efficient hæmostatic to restrain bleeding from wounded surfaces. "As an antiseptic dressing to wounds, to prevent the entrance of the germs of putrefaction, to check suppuration, and to promote healing," says Bartholow, "it has scarcely been inferior to the much-vaunted carbolic acid. It is an efficient means for procuring local refrigeration of an inflamed joint or swelling. Injected under the skin in the neighborhood of painful nerves, it has no inconsiderable anodyne power. This property may be utilized for the relief of myalgia and lumbago. It is more efficient than water, used by the method now known as aquapuncture. Enlarged tonsils, hypertrophied thyroid, and glandular swellings may often be slowly reduced and made to disappear by the parenchymentous injection of alcohol. This method is also applicable to the treatment of uterine fibroids."

In the same issue of the *Medical Times*, Dr. Henry C. Wood, in referring to alcohol as a food, has expressed the opinion that in many cases of illness, and in those periods of life when by reason of age the body waxes weak, alcohol is possessed of great virtues. He believes the moderate employment of stimulants is very useful to individuals past the age of sixty years. In the later years of life, even the narcotic influence of alcohol is of great value, easing the restlessness due to slight discomforts, and the suffering of nerve-failure incident to failing vitality. In chronic diseases, malt liquors have both their advantages and disadvantages. They represent food and drink, are less apt to be abused than are stronger liquids, and by virtue of their bitterness have some tonic properties. The tendency to grossness seen in beer-drinkers undoubtedly largely depends upon the solid constituents of the beer which is taken, and seems to indicate the proper medical use of malt liquors, namely, that they are especially to be employed in wasting diseases, *i.e.*, where there is a tendency to the loss of the bodily fat. As the malt liquors contain nutritive material, it is less necessary to give food with them than it is with whiskey or wines.

A Case of Croup Successfully Treated by the Introduction of a Catheter from the Mouth.—In the *British Medical Journal*, May 21, 1881, Dr. J. Wilson Paton has recorded a case of croup, which he claims to have cured by means of introducing a catheter into the trachea by the mouth, instead of performing tracheotomy. The case was a severe one, and would have ended fatally had no operation been performed. Tracheotomy seemed inadmissible, neither the case nor the surroundings being favorable for it. The introduction of a catheter into the larynx is easy and simple, and does not, according to Paton, take more than two or three seconds from touching the tongue with the spoon till the tube is in the trachea. When the tube had been in for forty-eight hours and a half it was removed, and at the end of the third day the child was so well as to be able to breathe freely without the tube, and was quite well before the tenth day after the operation.

Pathogenesis of Scurvy—Treatment by Hydrotherapy.—Dr. Costetti, convinced of the lack of therapeutical effect of other measures vaunted for the cure of scurvy, employs hydrotherapy. From 1873 to 1878 seventy-eight patients affected with this disease entered the military hospital of Bologna; all, even the most aggravated cases, recovered within thirty-seven days. Before beginning the treatment, the author convinced himself of the fact that the patients were without fever or heart disease. He contends that the malady depends upon an atony of the vaso-motor nerves of the skin and muscles, associated with a hemorrhagic tendency.

# THE MEDICAL RECORD:

## A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, October 1, 1881.

## CONCERNING ASYLUM REFORM.

Some criticisms have appeared, in one or two quarters, upon the attempts at asylum reform made here and elsewhere in the last few years. These criticisms have most unjustly misrepresented matters and bear evidences, if not of malice, at least of very great ignorance.

It has been affirmed in one journal that the organization of the Association for the Protection of the Insane was the signal for a decline in the prospects of asylum reform; and various sneers have been uttered regarding the efficiency of that organization. If that society has failed to do its best, it deserves criticism and should receive it. But there is no evidence of this put forward. We shall recur to this matter again; but meanwhile it may be sufficient to quote the words of a presumably unbiassed observer of its work, the President of the National Conference of Charities and Corrections, Mr. Frank B. Sanborn. In his annual address, last July, he said: "It seems to me that the formation of the National Association for the Prevention of Insanity and the Protection of the Insane, which took place last summer at Cleveland, has to some extent operated in the direction which its enthusiastic founders intended. Its task is a hard one, its methods are not yet perfect, nor is the experience of its members so great as it will be a few years hence; but it has made its mark on the public sentiment of the country, at least in this section."

This is a temperate endorsement, but it is enough to inspire confidence and to justify the past support that has been given it.

Some very severe criticisms have been made, also, concerning the Flatbush Insane Asylum, near Brooklyn. As the asylum in which treatment by non-restraint was first completely introduced in this country, its management has excited much attention. Believing as we do that the system of non-restraint is the one commended by reason and sustained by experience, we have praised the boldness shown in introducing it. And we are assured from many quarters that the experiment has been a most decided success. In the columns of a western medical journal, however, some one has used a report, made by the Hon. Ripley Ropes on the condition of the Flatbush Asylum, as the basis of an attack upon the new management. The injustice of this attack, we are assured, is very great. The Flatbush Asylum is greatly overcrowded, some of the buildings are old, and the grounds about them are limited. With these and other disadvantages that belong to all asylums under control of professional politicians, it is not surprising that the management should meet some obstacles and accidents. But the best has been made of a bad matter. The superintendent has the confidence of every one who is really acquainted with the workings of the institution. The complaints made by Mr. Ropes and quoted in the journal aforesaid are directed, not against the superintendent, but against the higher authorities, whose narrow-mindedness and parsimony so cripple the wisest efforts of Dr. Shaw. We are assured by Mr. Ropes that his criticisms did not refer to the superintendent at all. It must have been, therefore, either great ignorance or a petty spirit which could thus misinterpret the report and misapply the complaints. We trust it was the former. It will certainly be a misfortune if the progress in a much-needed reform becomes disturbed by any personal animosities, and it argues little sincerity when philanthropic energy so quickly succumbs to a private discontent.

### THE CASE OF PRESIDENT GARFIELD.

As is quite generally known, the Record intended, in this issue of October 1st, to present to its readers a surgical history of the case of President Garfield by his attending physician, Dr. D. W. Bliss, of Washington, D. C. Every endeavor has been made to prepare this report by the time expected, but the accomplishment of the task must be deferred for a day or two longer. Dr. Bliss has been seriously indisposed, but, notwithstanding this fact, has given himself up to the work with a determination to cause as little delay as possible. The moment it is finished it will be placed upon the press and issued in an advanced edition. We expect it to be ready on Tuesday next, and shall publish it on that date in the issue referred to—the issue of that week. In the meantime we have been compelled, in order to follow out the expectations of our subscribers, to go to press at once for the issue of this date.

It is unnecessary under the circumstances, perhaps, to apologize for the delay in this number, as up to the last moment we had hoped to use in it Dr. Bliss' report. As it is, there will be no possible interruption to the advanced publication of our next.

We have thought it more desirable also, and in better keeping with the great importance of the subject to be considered, to give Dr. Bliss a day or two longer for his work, than, for the sake of being prompt as to date, to have it go out in a condition not entirely satisfactory to him. We can assure our readers that Dr. Bliss is sparing no pains in giving all the salient points in the case, and in working it up in a most thorough manner from the standpoint of the medical attendant. It is also proper to state that the article will be copiously illustrated by drawings, taken under the supervision of Dr. Bliss, by Mr. Max Cohn, directly from the specimens, and that other articles bearing on the President's case will appear in that issue. The issue to be referred to is practically a delayed issue of that of October 1st, and will be in no manner delayed by the issue of the former.

---

### FUNCTIONAL MURMUR IN THE PULMONARY ARTERY.

Among the different kinds of cardiac murmurs, those originating in the pulmonary vessels have by common consent been considered as of rare occurrence and secondary importance. Dr. Nixon, however, in the current number of the *Dublin Journal of the Medical Society*, has recorded a series of observations tending to show that a functional murmur occurs quite frequently in the pulmonary artery. The observations of the author certainly deserve consideration, if only to call the attention of others to his rather novel claim. It would appear that this murmur may occur in many febrile affections. Thus, Nixon has frequently heard it in acute articular rheumatism, in typhoid fever, and in bronchitis. But he has likewise observed it in nervous diseases and in conditions of general debility. Finally, he states that it may be met with even in certain affections, which, in themselves trivial, nevertheless give rise to impaired nutrition. By a number of rather plausible arguments he explains why the sign has been hitherto so often overlooked or misinterpreted. He believes it to be caused by a diminution of tension in the artery itself. This would permit a twist or construction to be formed at its root during the ventricular systole.

While, therefore, this pulmonary murmur, admitting the comparative frequency of its occurrence, cannot in any sense be regarded as pathognomonic of a special disease, its presence may, nevertheless, serve to draw attention to the existence of a perhaps otherwise unsuspected malnutrition. For this reason it is well that we should be on the look-out for its presence. But, before we can class it with symptoms better known and more completely understood, we need corroborative evidence from others as to the frequency of its occurrence and the fact of its symptomatic significance.

### THE AMERICAN GYNECOLOGICAL SOCIETY.

The sixth annual meeting of this prosperous society was held in this city, beginning on Wednesday, September 21st, and continuing three days. The sessions were held in the Library Hall of the New York Academy of Medicine, and were well attended. The address of welcome was made by Dr. Fordyce Barker, President of the Academy, and contained a fitting comparison of the circumstances under which the society met in the same hall five years ago with those under which the present annual meeting was held, overshadowed by the nation's great calamity and loss. The papers, for the most part, had a practical, rather than a highly scientific value. To this general statement there were notable exceptions. The discussions were vigorous, and, as a rule, were not prolix.

The entertainments were all that could be desired. Lunches were given by Drs. Barker and Thomas, Skene and Byrne, and J. Marion Sims; and on the evening of the first day a brilliant reception was given by Dr. T. Addis Emmet. On the evening of the last day a reception was given by Dr. Isaac E. Taylor.

The President, Dr. William H. Byford, of Chicago, was unavoidably absent, on account of sickness; but he sent the annual address, which was well received, and contained words of good cheer for his brethren.

The duties of presiding officer therefore devolved upon the First Vice-President, Dr. Thaddeus A. Reamy, of Cincinnati, who discharged them with dignity and impartiality, and was assisted by the Second Vice-President, Dr. H. F. Campbell, of Augusta, Ga.

In the election of Dr. T. A. Emmet to the office of president the society has gracefully recognized the merit and deserved eminence of one of the most distinguished gynecologists of the New World.

Our readers will be furnished with an abstract of the proceedings at an early date.

---

A Case of Prolonged Somnolence that may serve as a companion-piece to that of the sleeping Hungarian in Pennsylvania is reported from one of the hospitals of Niederweisel, in Germany. The twelve-year-old daughter of an innkeeper fell into a deep trance in March, 1880, and continued in that condition for the entire remainder of the year. No medicine was given her, and the small quantity of nutriment that was prescribed had to be administered by forcing her mouth open. She had normal sleep at night, but during the day lay wholly motionless, and apparently without sensation or consciousness. At first much emaciated, her appearance subsequently became fresh and healthy. About the beginning of the present year she suddenly recovered her power of speech, and was soon wholly restored in other respects. She is now entirely well. It is also said that during the whole period of her suspended animation she was fully cognizant of everything that took place about her.

# Reports of Societies.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, September* 14, 1881.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

### INTERNAL STRANGULATION DUE TO A FALSE MESENTERY PROCEEDING FROM A REDUNDANT SIGMOID FLEXURE.

DR. E. C. WENDT presented a specimen which illustrated the above condition in a very perfect manner. He had removed it from the body of a young Spaniard, who had died the night before. The history, so far as he had been able to ascertain it, was as follows: The patient had come to this city from Mexico about two weeks ago. He had always enjoyed perfect health, and was endowed with a splendid physique. About noon on the 7th of September he was seized with a sudden and sharp pain in the right side of his abdomen. During the course of that day it seemed to diminish in intensity, so much so that he is reported to have enjoyed a bath in the evening, and a hearty supper rather late at night. At eleven o'clock, however, he again experienced a very severe pain to the right of the umbilicus. Vomiting now speedily set in, and continued with varying intensity up to the time of death.

Dr. Rengifo saw him on the following day, when purgatives were freely administered and morphine in small doses prescribed. Enemata were also used, but the absolute constipation continued. Meantime, marked constitutional depression was developed; the abdomen became tensely swollen and tender, and the patient's condition grew agonizing. Dr. Cisneros was now called in, and the "purgative plan" continued. The patient growing steadily worse, with unmistakable symptoms of peritonitis, Dr. L. Weber was asked to see the case in consultation. This was on the night of the 12th inst., near eleven o'clock.

Acute intestinal obstruction being apparent, Dr. Weber determined to perform an exploratory laparotomy on the following morning. When Dr. Wendt saw the patient, together with Drs. Weber and Weir, his pulse was already feeble, and, though the abdominal pains had been somewhat controlled by anodynes, the mental stress was great and the general condition far from reassuring. Nevertheless, it was decided to give the patient the chance of life by a speedy operation. But the anæsthetic produced an alarming syncope, and the proposed plan of surgical interference had to be abandoned. Later on that day he again rallied. The tympanitic distention of the intestines was then relieved by several punctures. But the good effects of this measure, together with liberal stimulation, were only temporary. He died that night, apparently exhausted.

At the autopsy the signs of a moderate diffuse peritonitis were found. Recent adhesions, which were readily separable, existed between adjoining abdominal organs. Low down in the pelvis a piece of strangulated gut, showing imminent gangrene, was discovered. The strangulated portion corresponded to the lower end of the ileum, being only about three inches distant from the cæcum. Its length was about seven inches. The cause of the strangulation was found to be a round opening in a false mesentery attached to a redundant sigmoid flexure. Through this opening, which barely admitted the exploring finger, the intestine had slipped and become permanently fastened. The band extended from near the crest of the ileum, on the left side, to the internal inguinal ring on the same side. At the latter point it became lost in a puckering of the pelvic peritoneum.

Dr. Wendt was inclined to regard this thick and completely organized band, which represented the false mesentery, as a congenital malformation. Perhaps it had some connection with the unusual length of the sigmoid flexure, which showed a redundancy of over a foot in length. He thought such a condition of the sigmoid flexure was extremely rare in adults, though Dr. Jacobi had pointed out its comparative frequency in childhood, where it became a frequent source of obstinate constipation.

Doubtless the opening in the false mesentery had existed many years. Certainly there must have been a peculiarly unfavorable constellation of circumstances before the gut could have slipped through such an aperture. It did not appear from the history that any violent muscular effort or other bodily strain had preceded the fatal accident. The case was interesting also from a surgical point of view. The question at once suggested itself, whether the patient's life could have been saved by a sufficiently early operation. Probably the hidden position of the strangulated piece of intestine would have rendered the laparotomy a prolonged and dangerous operation. On the other hand, after a discovery of the mechanical cause of the obstruction, the mere cutting of the strangulating band would have been a very simple and harmless procedure. It was to be deplored that we had no means at our command enabling us to locate with more reliable exactitude the situation of an obstruction, in cases such as the present one.

DR. RIPLEY asked, if, in the treatment of the case, water was used to distend the intestine and remove fecal matter.

DR. WENDT replied that it was, but that no fecal matter escaped; there was only a yellowish discharge. He considered the opening, through which the loop of intestine had passed, to be congenital. The sigmoid flexure, as already stated, was extremely long, assimilating the condition which had been described by Professor Jacobi as a cause of obstinate constipation in children.

DR. PEABODY remarked that a similar case came under his notice some three years ago, the patient dying of an internal strangulation of a diverticulum of the ileum. In this case there was an adhesion uniting a part of this diverticulum with the mesentery, leaving an open space of perhaps two inches, through which seven feet of the intestine, chiefly of the ileum, passed and became strangulated. At the autopsy even it was difficult to discover the lesion, and it was suggested to his mind that any attempt at an operation would have proved unsuccessful. He did not think any surgeon would dare to handle the intestine so freely as was necessary to find the constricting band.

DR. TAUSZKY thought that, in the case reported by Dr. Wendt, the patient might have recovered if the band had been divided, and that the operation was feasible. He had seen reference made to a case in which a German surgeon removed several inches of intestine which was gangrenous, stitched the divided ends together, and the patient, recovered. Without an operation all these patients died, hence any operation which held out even a remote chance of recovery should be undertaken. As regards col-

lapse interfering with the progress of such an operation, he thought the intravenous injection of ammonia might overcome that difficulty. Experiments had shown that it was possible to keep patients alive by this means half an hour longer than they otherwise would have lived, and thus enabled them to converse with their friends. He thought in extreme cases an operation ought always to be undertaken. If the patient was placed with the pelvis elevated as in ovariotomies, the intestine would fall away so as to bring the parts within the pelvis into view.

Dr. White inquired what form of ammonia was used, and its strength.

Dr. Tauszky replied that the ordinary aqua ammonia, diluted one-half with water, was used.

The President inquired if it would not be more difficult to expose the intestine in such a case as reported, than in a case of ordinary ovariotomy.

Dr. Wendt remarked that the small intestine was enormously distended with gas, and he thought the first incision into the abdominal cavity would have resulted in its bulging out of the body. This he thought would increase the danger of the operation. At the autopsy the distention was less than during life, and even then it was difficult to get the intestine back, notwithstanding the ordinary extensive incisions for post-morten examination were made, and it was necessary to make punctures into it before it could be returned.

Dr. Jacobi remarked that Dr. Wendt had alluded to the fact that the sigmoid flexure was very long in the fœtus, new-born, and children generally, up to the age of five, six, or seven, and that this gave rise to very serious constipation. He was not aware that a very long sigmoid flexure was common in the adult; certainly not so long as described by Dr. Wendt. He thought it very probable that the presence of the opening was due to a congenital defect, and perhaps it had something to do with the leaving intact of the disproportion of parts of the intestinal tract. It seemed to him that the connection between the two was not improbable. It was simply a suggestion on his part; he had no explanation to offer, but was desirous of learning whether anything was known on the subject.

Dr. Wendt thought the suggestion a very plausible one. It might be, also, that this band was the result of early fetal inflammation, which finally led to the continuance of the disproportion.

Dr. Jacobi said that he had tried to ascertain if there was an adhesion between the sigmoid flexure and this band, but Dr. Wendt had said there was none; hence the difficulty.

The President thought the appearance of the ring was in favor of its being of congenital origin. It did not look as if it were caused by inflammation; otherwise there would have been inflammatory changes elsewhere. As to the cause of such congenital openings, we knew very little.

Dr. Jacobi presented a specimen of

PULMONARY CONSUMPTION IN THE YOUNG.

There were some peculiarities in the occurrence and appearance of pulmonary consumption in the young. First, it was a statistical fact that, of a hundred deaths from pulmonary consumption, about five or six per cent. occurred below the age of five years; two or three per cent. between five and ten; two or three per cent. between the ages of ten and fifteen; twenty to twenty-five per cent. between the ages of fifteen and twenty-five; twenty to twenty-five per cent. between the ages of twenty-five and forty, and the remaining above forty. There were some peculiarities which it was not worth while to overlook. Among these was the fact that the destruction of pulmonary tissues was not so extensive in the young as in those advanced in age; that children died before they developed large cavities. As a rule, the symptoms belonging to large cavities, and all the other anatomical conditions of pulmonary disease, were not so noticeable in children as in those advanced in years. Another point might be that hemorrhages in children were not so frequently among the clinical symptoms, and particularly hemorrhagic infarctions were by no means common; they were rare.

A specimen of lung was presented, taken from a child between the ages of ten and eleven, who had been admitted to the doctor's ward in the hospital, discharged, readmitted, and finally died in the hospital. There was one peculiarity about the child that appeared to have marked him out for pulmonary trouble. He had, in contradistinction to his family, who were healthy, a narrow chest, due to excessive shortening of the cartilages of the ribs, particularly in the upper part. It was known that early ossification had a tendence to end in pulmonary disease, simply because the development of the chest was defective, and in advancing years the lungs could not expand. This, he believed, had been proved by no one better than by Freund, some fifteen years ago. There was no ossification in the case reported, but the cartilages of the ribs were excessively shortened. In the early part of the attack there was considerable dulness above the clavicles, toward the median line, attributed to and dependent upon great swelling of the bronchial glands. He should have further said that miliary tubercles were rarely found during the first year of life. Afterward they were for some years more frequent.

In examining the specimen presented, the first thing noticed was the implication of the pleura all around, diaphragmatic as well as pulmonary; second, the density of the lung-tissue. In the upper part of the apex was a cavity lined with a pyogenic membrane. Several cavities contained a considerable amount of dry, dense hemorrhage. In one cavity, very near the pleura, with no pyogenic membrane surrounding it, there was a fresh deposit of coagulated blood. In the midst of a good deal of hard tissue were found many small cavities—dilated bronchi. A number of other cavities were the result of hemorrhage which had taken place at some previous time. Very few of the adjoining glands but had undergone hyperplastic enlargement and pigmentary discoloration, and showed the beginning of caseous degeneration. The walls of the bronchial tubes were very much thickened. The child had been sick a number of years, and had had plenty of time to develop the different sorts of bronchitis and peribronchitis. The patient had suffered from a complex condition: first, from scrofula and general adenitis, from caseous pneumonia, bronchitis, dilatation of the bronchi, hemorrhagic infractions, and excessive chronic pleuritis.

Dr. Peabody inquired what was the condition of the other lung.

Dr. Jacobi replied that there was a great deal of peribronchitis, but no large cavities.

Dr. Ripley inquired if there were strong adhesions to the chest-wall.

Dr. Jacobi replied that the adhesions were particularly strong, so that in removing this lung a rupture took place.

Dr. Ripley asked which of the lesions was supposed to be primary.

Dr. Jacobi thought it probable that pneumonia was the original lesion, as in the beginning of his observations the superclavicular dulness was noticed, and had been permanent.

Dr. Ripley thought the specimen presented resembled several which he had seen, in which the original lesion was pleurisy. He had reported a case in which the original lesion was subacute pleurisy. The patient had empyæma. Finally, the fluid was absorbed, and after a year or so a cough was developed. The patient was admitted into the hospital, and finally died. At the autopsy a condition very similar to the one presented in the specimen exhibited was found. The lungs were peeled off from the ribs, the impression of the latter remaining in them.

### SOME POINTS AS TO THE DIAGNOSIS AND PROGNOSIS IN CARCINOMA, ADENOMA, AND SARCOMA OF THE MAMMA.

The President presented a large number of microscopic slides illustrating cases of these and other changes in the breast. He observed that, in hastily looking over his notes and taking account of one hundred and one growths and conditions simulating them, as occurring consecutively, the following figures were found to represent their comparative frequency: Scirrhous carcinoma, 80; medullary carcinoma, 3; colloid, 2; sarcoma, 4; cysts, 4; adenoma, 3; fibroma, 3; gumma, 1; chronic abscess, 1; total, 100.

He first showed microscopic sections of a scirrhous carcinoma, which was worthy of some attention. The history of the case was as follows:

A. M. R——, now sixty-three years of age, formerly a nurse in St. Luke's Hospital, first detected a nodule in one breast in December, 1873. It was removed in the March following by Dr. George A. Peters, and has never returned. Her health also is good. She has therefore enjoyed an immunity for more than seven years. This example of an operation performed three months after the inception of the disease argues well for the prevailing theory that early operations tend to increase the expectation of life.

A still more remarkable case, however, was that of a lady now living in Orange, N. J., from whom a mammary tumor was removed by the operator already mentioned, in 1876. With her the disease appeared nine and a half years ago. But this case has been surpassed by one occurring in the private practice of Dr. Weir, where, at last accounts, the disease had persisted for more than sixteen years, the patient having undergone several operations, but still preserving fair general health. In this connection it was interesting to know that he had found the average duration of life in scirrhus, in the various parts of the body accessible to the knife (fifteen cases), to be about twenty months.*

#### SARCOMA OF THE BREAST.

He next exhibited a microscopic slide removed from a patient at St. Luke's Hospital, Feb. 19, 1873. The history was as follows: About two years before admission, the patient observed a small lump in the lower part of the right breast. It grew gradually in size, but gave no pain until the latter part of January, 1873.

On examination the following points were noted: the breast surface was nodular, but the skin was nowhere broken, and there was no retraction of the nipple. It was also freely movable, except at one point, where it seemed to be attached to the skin. Pain lancinating, but intermittent; tenderness to the feel. No enlargement of axillary glands. General condition good. The tumor was removed by operation and the patient discharged cured. It was noted at the subsequent examination that in consistency the growth was semi-solid; that it was round, soft, friable, lightly attached to its capsule, contained cysts, and was undergoing softening at the centre, and had a dull, pale color. The cavities contained a glutinous substance.

Microscopically the tissue was composed of abundant rounded corpuscles embedded in a scanty basis-substance, which was occasionally seen to be fibrillated. Remains of duct-structure and vessels were found in some parts of the growth. A qualified prognosis was given in this case, the statement being made that "in many cases there is no recurrence after removal." It is therefore interesting to know that this patient is still in good health and has had no recurrence. Immunity over eight years.

It was added that in another case of sarcoma, of which there was recent information, the patient, a widow, was first attacked in her fiftieth year. It was characterized by dull, stinging pains, and there was discharge of watery fluid. The glands also were enlarged. It was removed July 12, 1872 (Drs. J. L. Little and C. A. Loring).

There has been no return, and the patient merely finds that the cicatrix is apt to be sensitive at times. Immunity over nine years. These facts are interesting now, as we are attempting to classify these mammary neoplasms so that a clinical distinction and prognosis may easily be made. It is well known, however, that both of these points are still wrapped in much obscurity. It will be observed, however, that the nodular outline, semi-solid consistency, discharge from the nipple, which was not retracted, and partial adhesion to the skin, are qualities that have been claimed for sarcoma, while the naked-eye appearances on sections, such as the appearance of a soft, friable, sound, capsulated tumor, undergoing cystic and fatty change, are still further indications that the tumor was sarcomatous.

#### ADENOMA OF THE BREAST.

The President next exhibited slides illustrating an adenoma of the same locality. This neoplasm, it was urged, is more difficult to diagnosticate, either clinically or by the microscope, mainly because hard to differentiate from fibroma. The case was as follows: E. L——, thirty-eight years of age, born in Ireland, single, was admitted to St. Luke's Hospital, March 20, 1880. Eighteen months previously she began to suffer from slight pains in the left breast, and shortly afterward detected a lump, the size of a hickory-nut, in the upper portion. The nodule gave pain at the menstrual epoch chiefly, and extended to the left shoulder and arm. On admission the whole breast was found enlarged and quite red, particularly on its under surface. A special mass, hard to the feel, was detected at the centre. Patient had previously suffered from rheumatism and dyspepsia. There was no discharge from the nipple. The tumor was removed, and has not recurred since. In another instance, where he also had made the microscopical examinations, there had been a recurrence after six years' interval. The hardness of adenoma was thought to be peculiar, and intermediate between sarcoma and fibroma. The outline

* Observations on One Hundred Cases of Carcinoma, by Drs. T. E. Satterthwaite and W. H. Porter. N. Y. Med. Jour., 1879.

was found to be somewhat uneven, but the new formation was intimately connected with the breast. It is also apt to occur earlier than sarcoma. On section it will look lobulated. Discharge from the nipple is not an important sign, as it may occur in sarcoma, adenoma, or fibroma. Its growth is slow. If, for any special reason, the growth assumes any active change, perhaps as the result of an injury, the glands may become enlarged, without, however, indicating that a metastatic deposit has taken place there.

Dr. Tauszky remarked that the President, in describing the difference between adenoma and carcinoma, did not say that in carcinoma ducts were found, and that in adenoma they were absent.

The President said there were two forms of tumor having an epithelial type—carcinoma and adenoma. Adenoma seemed to originate from the ducts—to be, in other words, an extension of the normal duct-structure, though in such cases the new gland-substance was not perforated centrally as ordinary ducts were. Carcinoma, on the other hand, was a perverted growth, which, originating in the epithelium of the ducts, spread from its points of origin through the medium of the lymphatics, and, therefore, assumed the outline of those spaces or channels which form networks throughout the connective tissues.

Dr. Tausky added that he had demonstrated that sarcomatous formations originate in epithelium, as well as in connective tissue.

The society then went into executive session.

## Correspondence.

### HOW TO PREVENT SEDIMENT IN MAGENDIE'S SOLUTION.

To the Editor of The Medical Record.

Sir:—In your issue of the 3d instant, under the heading "Suggestions regarding Hypodermic Injections," Dr. C. Mason, of Peekskill, N. Y., asks: "Now, as to the solution (Magendie's), who can say that they can prevent a sediment from forming when it has been made for a number of days?"

In answer, I would like to state that I can do it without the least difficulty, by adding to the solution (Magendie's) a little carbolic acid, say two drops of the acid to an ounce of the solution.

Since I adopted this combination, about ten years since, I have not had an abscess, nor even a cellulitis, form from the result of a hypodermic injection of morphine. The device was given to me by a member of our profession addicted to the morphine habit by the hypodermic method.

He had been a frequent sufferer from abscesses until he set to work to study the flocculent deposit we are all so familiar with in Magendie's solution, after it has been prepared a few days. This deposit, he said, was a vegetable fungoid, which could be distinctly observed under the microscope, and was, in all probability, one of the irritating causes which light up suppurative cellulitis, in the course of hypodermic injections of this liquid.

I have seen this growth repeatedly under the microscope, and there can be no question about it; it cannot form in a carbolized solution of the drug.

I believe the introduction of this vegetable organism is the sole cause of the inflammatory results of these hypodermic injections, for its destruction, or rather, its absence and prevention, has given me, so far, absolute immunity from such disastrous results. I think many physicians carbolize their Magendie's solutions in this way now, but up to the time I heard of it I never knew it was used, and it was novel to every one to whom I mentioned it.

I have known several "hypodermic morphine takers" whose bodies were marked all over with the cicatrices of abscesses, and who always had one or two points on hand in the process of suppuration, so that they had come to look for them as the thorns to their roses; but, upon prescribing for them this carbolized solution, all abscesses have ceased, and their comfort in the pernicious practice has been complete and abiding.

To those who may fear the toxic effect of the carbolic acid administered in this way, I would say it is positively nil. I have used carbolic acid hypodermically quite extensively in the treatment of acute inflammatory rheumatism, intermittent fever, puerperal septicæmia, and traumatic fever (probably septic), in quantities of two drops in two drachms of water every three hours, without ever having seen its toxic effect. I also frequently prescribe it *per orem* in doses of three or four drops, well diluted, for a variety of conditions, and have never yet seen its toxic effect upon the disease for which it was intended.

I mention these facts in my observations in order to dispel the fear which some may have in using it, even in the minute doses recommended with morphine.

I think if the doctor will try the carbolized solution, he will be spared the labor and annoyance of having to prepare his morphine solution afresh every time he is called upon to use a hypodermic injection of it.

I have just examined the remnants of a three-ounce vial of the carbolized solution. This has been prepared over three months, and there is not a particle of deposit in it.

Yours respectfully,
Walter P. Gillette, M.D.

149 West Twenty-third Street, New York,
September 19, 1881.

### THE SPIDER AS AN ANTIPERIODIC.

To the Editor of The Medical Record.

Dear Sir: The paragraph headed "The Spider's Web as an Antiperiodic," in the Record of July 23d, brought to my mind the story told me by a sailor, who, in the course of his journeyings to and fro upon the Lakes, had frequently to pass through the Welland Canal, which runs through a very malarious district; and upon almost each occasion he found himself possessed of—if not of a devil, at least a cousin-german: an ague, much to the detriment of his health, as well as his exchequer, by the purchase of that potent but high-priced exorciser, quinine.

On one occasion, while dining at a canal-side hostelry, he became possessed of his old-time enemy. A friendly sailor, on inquiring what was wrong, informed him that he would cure him within an hour, and that so effectually that he would *never* have another seizure.

His remedy was near at hand and inexpensive, for, after a cruise around the room, he returned with a lively specimen of the common house-spider, which was to be taken as a living sacrifice to eternally appease that great Goddess of the Shakers, malaria.

He stated it was important you should follow out the directions.

You first catch, not your rabbit, but your spider, place it carefully in the palm of one hand, and with the fingers of the other, gently manipulate him or her (both sexes being, I believe, efficacious) until the legs are well tucked in, and it assumes a pill-like shape, when all is ready for *le grand coup*, viz.: swallow it *alive* with as good grace as you can muster. My informant stated that the dose made him feel rather sick, but that he began to feel better in half an hour; that from that day to this (some years) he has never had an attack of the ague, and that it has proved equally efficacious with many others.

If two grammes of the product of the spider (spider's web) can cure an ague, how much more efficacious should the swallowing of the whole manufactory be?

Is it not quite possible that the family of the Arachnidas may secrete some virus that is antidotal to the poison of malaria? If so, it will merely become a question with the sufferer whether he prefers his ague to this heroic insectivorous remedy.

I am, yours very truly,

ALGERNON WOOLVERTON.

HAMILTON, ONT.

## MASSE'S ANATOMICAL PLATES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the MEDICAL RECORD for the 10th instant appeared a notice of the new edition of "Masse's Anatomical Plates," edited by Professor Ranney, and published by us.

Your reviewer states that "'Masse's Manual' is not even alluded to in connection with this edition."

As Masse's name appears in full on the title-page, and also on the back of the book, and as the editor commences his preface by saying that "he has the pleasure . . . . etc., . . . . of presenting to the profession of the United States an edition of the beautiful Anatomical Atlas of Professor J. N. Masse, of Paris," we are at a loss to understand how your reviewer could have misled himself into making so unfounded a statement; and as the statement is calculated to do injury to our editor and ourselves, we must ask you to give equally conspicuous space in the RECORD to this correction.

The omission referred to in the "Publisher's Note," in the first copies of the work sent out, was (as said notice duly stated) of the name of Professor Pattison, the editor of the first American edition.

This omission (which of course should not have occurred) was, however, promptly corrected before any copies of the work had been reviewed.

We regret that your reviewer should have informed himself so insufficiently as to have been led into committing an injustice, but we can of course depend upon your readiness to set the matter right, so far as may now be possible. Yours truly,

G. P. PUTNAM'S SONS.

"A THERAPEUTIC PEARL AT RANDOM STRUNG."—London *Truth* says that a good way to avoid headaches after midnight balls is to dilute the champagne with seltzer. A better way is to dilute the seltzer with a few drops of the aromatic spirits of ammonia. (Signed) D. Hayes Agnew, Frank H. Hamilton, D. W. Bliss, J. K. Barnes, J. J. Woodward, Robert Reyburn, Jane Swisshelm.—*Ex.*

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September* 17, 1881, *to September* 23, 1881.

REED, W., Capt. and Asst. Surgeon. Assigned to duty with Light Battery "A" Second Artillery, ordered to leave Washington Barracks, D. C., on Sept. 20, and march to Yorktown, Va. S. O. 165, Department of the East, Sept. 16, 1881.

TAYLOR, A. W., First Lieut. and Asst. Surgeon. Relieved from temporary duty at Fort Lyon, Col., to proceed to Fort Dodge, Kansas, there await arrival of escort conducting Little Chief and his band to Department of Dakota, and report to the commanding officer as medical officer. After reaching Sidney, Neb., on return trip, to proceed direct to Fort Leavenworth, Kansas, and report to the Medical Director. S. O. 188, Department of the Missouri, Sept. 16, 1881.

* Two were emigrants.

THE AMERICAN GYNECOLOGICAL SOCIETY.—At the sixth annual meeting of this society, just held in this city, the following papers were read: "Acute Diffuse Hyperæsthesia of the Peritoneum following Minor Gynecological Operations and Manipulations," by Dr. S. C. Busey, of Washington; "Exploratory Puncture of the Abdomen," by Dr. H. J. Garrigues, of New York; "Notes on Cases of Pelvic Abscess," by Dr. G. H. Lyman, of Boston; "Genital Renovation, Particularly by Kolpostenotomy and Kolpoeccpetasis, in Urinary and Fecal Fistules," by Dr. N. Bozeman, of New York; "Forcible Elongation of Pelvic Adhesions," by Dr. E. Van de Warker, of Syracuse; "Esthiomène, or Lupus of the Vulva, with Cases and Colored Illustrations," by Dr. I. E. Taylor, of New York; "Bursting Cysts of the Abdomen," by Dr. William Goodell, of Philadelphia; "Erysipelas in Childbed without Puerperal Peritonitis," by Dr. H. F. Campbell, of Augusta, Ga.; "Expansion of the Bladder over the Surface of the Abdominal Tumors and its Attachment to them, or to the Abdominal Walls as a Complication of Laparotomy," by Dr. T. Gaillard Thomas, of New York; "A Case of Partial Inversion of the Uterus, Caused by a Fibroid Polyp," by Dr. T. A. Reamy, of Cincinnati; "Axis Traction of the Obstetric Forceps," by Dr. A. H. Smith, of Philadelphia.

The following were elected officers for 1882: *President:* Dr. T. Addis Emmet, of New York. *Vice-Presidents:* Dr. G. H. Lyman, of Boston, and E. Noeg-

geratli, of New York. *Council:* Drs. H. J. Garrigues, of New York; James D. Trask, of Astoria, N. Y.; George H. Bixby, of Boston; and G. J. Engelmann, of St. Louis. *For Honorary Fellows:* Tarnier, of Paris; Braxton Hicks, of London; and Winckel, of Dresden, were elected; and for *Active Fellows:* Drs. William M. Polk, C. C. Lee, W. R. Gillette, and F. P. Foster, of New York, Dr. E. W. Sawyer, of Chicago, and Dr. B. B. Browne, of Baltimore. The next annual meeting will be held in the city of Boston, in the third week of September, 1882.

Fighting Unlicensed Practitioners.—Two men, father and son, of the name of Grindle, were recently brought before the police court by Dr. A. E. M. Purdy, who charged them with practising without a license. They both exhibited regular licenses to practise, in which it appeared that they were graduates of the American University of Philadelphia, the establishment run for a long time by Dr. Buchanan. Young Grindle admitted that he had advertised under the name of Dr. Dyer, and it was contended by the prosecution that the defendants each answered to the name of Dyer if any patient called. The specific charge against young Grindle was that on the 13th of August he had prescribed for one McCarthy, but the witness failed to identify him satisfactorily, and the accused said he could prove that on the date mentioned he was in Maine. Both the Grindles were discharged.

Another person named Morant was also brought before the court. He was identified by Charles McCarthy as having prescribed for him on the 15th instant, and given him a bottle of medicine for which he paid one dollar. Morant denied that he had prescribed for McCarthy, and said he had merely given him the medicine under the direction of Dr. Grindle. Justice Morgan required him to give $300 bail for trial. John Lauritz, the man who achieved notoriety some years ago as the bondsman of the notorious Mme. Restell, gave the required security and Morant was allowed to depart.

Two druggists were also brought up, charged with counter-prescribing. They were reprimanded and discharged.

Registration of Vital Statistics in Delaware.—A law has been enacted by the Delaware Legislature requiring the registration of all births, marriages, and deaths in the State.

Consumptives in the Adirondacks.—Two or three deaths from consumption are reported from the region near Lake Placid within a week. Through the summer nineteen deaths are reported throughout the Adirondack region among the cases sent there for benefit. This mortality is probably caused by the great dampness near the lakes, the violent changes of temperature peculiar to the country, and the poor nourishment usually obtained in the houses and camps. Only a few have found relief from this disease in those mountains.

Malaria in New England.—There seems to be strong evidence that malaria is gradually invading New England, passing up the Connecticut Valley. It has appeared in the vicinity of Hartford, of Springfield, and has even been quite prevalent in some of the Vermont towns situated on the river.

The frequent appearance of the disease in an almost epidemic form disproves the idea that malaria is increasing because the health of the people and power of resistance is less.

The Vienna Cases of Gastrotomy for Cancer have all terminated fatally, except one. This is the case operated on by Billroth's assistant, Woelfler, in April last, in which, according to the operator's statement, the malignant disease was confined absolutely to the stomach, all other organs, including the lymphatic glands, being apparently unaffected. As may be imagined, this patient will be watched with anxious interest by all friends of the operation. Woelfler has recently published a monograph, with plates, describing the operation and modifications as performed by Billroth, published by Braumueller & Co., Vienna.—*Cor. Chicago Medical Journal and Examiner.*

Coffee and Sugar.—M. Leven, of Paris, has been making some investigations into the action of coffee on the stomach of dogs. He concludes that coffee alone tends to cause gastric anæmia and indigestion, but given with sugar, such effect is not produced.

Dying in the Hospitals.—The following resolution has been introduced into the Chambre des Députés: "Every physician who shall die in the hospitals, while treating an epidemic disease, will be considered as having died upon the field of honor, and his widow or his children will receive a pension equal to that of the soldier who has died upon the field of battle, that is to say, the double of the ordinary pension."

Under-fed.—According to Mrs. Amelia Lewis, one-quarter of the world is over-fed, one-quarter is is properly fed, and one-half is under-fed.

Our Croton Water, according to Dr. Cutter (*Food and Health*), furnishes just now a microscopical menagerie of the most varied kind. In one week sixty-five different specimens were observed and identified. The peredinium candelabrum and the scenedesmus quadricauda are the names of some of the most aggressive monsters.

What with the resin in his and unspeakable organisms in the drinking-water, the New Yorker has a hard time of it.

The Neurotic Theory of Asthma.—Dr. Burney Yeo (*Practitioner*), in arguing for the view that asthma is a neurosis essentially, concludes with the following: "I would like to point out one analogy with a well known nervous and hysterical phenomenon which has, I think, never yet been remarked upon. I allude to the great distention of the lungs which is observed in many cases of asthma, a distention which has been often thought difficult of explanation; but may we not trace an analogy between this great distention of the lung in asthma and the very remarkable and hitherto unexplained tympanitic distention of the intestines often encountered in some cases of hysteria?"

The Regulations Regarding Antiseptic Treatment at Billroth's Clinic.—According to Dr. Bauer, in the St. Louis *Clinical Record*, these are, more especially in laparotomy operations, as follows: "The *first* rule observed is *scrupulous cleanliness* of the operating and sick-room. If the slightest doubt is entertained as to their purity the rooms are sprayed with five per cent. carbolic acid for several hours. This measure is intended to clear the air in the rooms of bacteria and to precipitate suspended germs. The *second* rule applies to the *thorough disinfection* of all articles of dressing, instruments, the hands of the surgeon and of his assistant, to prevent *contact infection*. The sponges to be used should be new

and soaked for several days in a five per cent. carbolic acid solution. The *third* rule permits but *one assistant*, and he and the surgeon alone are allowed to handle intra-peritoneal parts. The *fourth* rule commands *carbolized ablution* of the abdominal integuments, but excludes the spray during the operation as useless, if not directly noxious, on account of the rapid absorption of carbolic acid by the peritoneum and the consequent danger of poisoning. The *fifth* rule is directed against the danger of *spontaneous infection*."

THE PRESENT RAPID INCREASE OF "ELEGANT PHARMACEUTICAL PREPARATIONS" is criticised by Dr. Leasure, in his address before the Minnesota State Medical Society, as follows: "Some of the new journals are ostensibly medical journals, but are really little more than advertising adventures, to bring into notice certain new remedies, or proprietary mixtures or pills, to the profit of the inventor or manufacturer. Some of these are sent us regularly as specimens, till our tables are littered with testimonials from leading physicians and theologians bearing witness to the efficiency of certain proprietary medicines or mineral waters. Even that much-abused creature, cod-liver oil, is subjected to the tortures of the alembic, and comes to us bespangled like Joseph in his coat of many colors. There has never been one of these tangential offshoots of Hippocratic medicine that has not lopped off some crudity from the tree of knowledge or left some shoot of truth that, properly engrafted, has not borne good fruit in after years."

AN ASYLUM FOR THE CRIMINAL INSANE is being built by the State of Missouri at Fulton.

THE BRAIN OF THE MURDERER REDEMEIR—DIAGNOSING IMBECILITY AFTER DEATH.—The case of the murderer Redemeir has excited much interest in St. Louis. The man had always been quiet and peaceable, but taciturn. One day, without apparent motive, he took out a pistol and shot a brother workman, killing him at once. On trial, the plea of insanity was unsuccessfully urged, and the man was condemned to death. The St. Louis *Clinical Record* took the ground very strongly that it was a case of judicial murder. The brain of the man was obtained and sent to Dr. E. E. Spitzka, of this city. His conclusions, from a careful examination of it, are as follows: "From the generally low type of cerebral structure, the atypical asymmetry of the hemispheres and the great ganglia, the persistence of an embryonic feature in the occipital lobe, the thickness of the barren cortical layer, and the presence of another anomalous feature in the cortical elements, only one conclusion can be drawn, namely, that the subject from whom this brain was obtained was an imbecile; and in the light of our knowledge of the life history of persons in whom similar anomalies have been discovered, an imbecile who should be classified in that large group of hereditarily degenerated subjects in whom, with the general background of imbecility, are often found either epileptic and epileptiform seizures, morbid impulses or delusions, moral perversion and pathological fury. So far as the photograph in my possession permits of a conclusion, this subject had not only asymmetry of the face, but also the general expression of the subjects of these conditions."—*St. Louis Clinical Record.*

DARWINISM AND THE EXTINCTION OF GREAT MEN.—Dr. Jacoby has recently published a new book entitled: "Études sur la Sélection dans ses Rapports avec l'Hérédité chez l'Homme." It gained the prize offered by the Madrid Royal Academy of Medicine in 1874 for a work on the hereditary influence of selection upon the human race. It may be doubted, however, whether the book can be correctly described as a contribution to Darwinism. Darwin's theory is essentially that of the survival of the fittest and the gradual evolution of higher types, including man himself, from lower organisms. But Dr. Jacoby gives a very appalling explanation of the reason why there are no more Homers and Shakespeares, and one which scarcely seems to harmonize with the theory which evolves the brain of man from the tip of a plant radicle. In brief, Dr. Jacoby's conclusion is that whenever any member of a (human) family becomes illustrious, that family pays by rapid degeneracy and ultimate extinction for the (comparatively) momentary *eclat* acquired. Humanity hereafter will not be the posterity of the powerful, the rich, the intelligent, the learned, the energetic, but of laboring peasants, necessitous *bourgeois*, humble and little people. The future belongs to physical mediocrity; every conquest of intelligence hastens the extinction of the race, and the school board is the precursor of a depopulated world.

DR. CHARLES S. ROY has been made Professor Superintendent of the Brown Institute in place of Dr. Greenfield, resigned.

THE MEDICAL NIGHT-SERVICE, which is organized in twenty arrondisements of Paris, during the year 1880 visited 1,770 patients, of whom 651 were men, 883 women, and 236 children under three years.

ANOTHER FRENCH PHYSICIAN, Dr. H. Clozel de Boyer, has died from diphtheria contracted in the course of his duties at the Paris Children's Hospital.

THE EUROPEAN MESMERIZER, Hansen, who has been giving *séances* before the medical societies of Austria and Prussia, has been forbidden to hold any more, on the ground that he injures the subjects whom he employs.

AN ALBANY PHYSICIAN DROWNED.—Dr. Harris S. Fellows, who had been missing for two days, was found drowned August 31st. Dr. Fellows was identified with the Greenback-National Party, and was well known throughout the State.

ORIGIN OF YELLOW FEVER.—Dr. Manuel Da Gama Lobo, of Rio Janeiro, physician to His Majesty the Emperor of Brazil, has been prosecuting some microscopic investigations relative to the land origin of yellow fever. He has found at Vera Cruz, Mexico, and Havana, Cuba, sufficient evidence to warrant him in stating that these localities are fruitful sources of a poison which causes the disease. The toxic agent is derived from a species of infusoria, the *opunsia Mexicana*, which belongs to the family of *bacillæ*.—*Sanitary News.*

THE REGISTRATION LAW IN PENNSYLVANIA—DISCOVERY OF A BOGUS MEDICAL DIPLOMA.—The clerk who has charge of the registry of physicians' diplomas under the new law has been very busy. He has been registering about twenty diplomas a day, and by September 1st had already a list of nine hundred names. There is a fee of one dollar exacted for the registration.

About a month ago a Dr. T. F. A. Reinhardt presented a diploma purporting to come from the University of Wurzburg, Germany. It was duly registered, and a certificate to that effect was handed to

him as an evidence that he had complied with the recent act of Assembly. After the copy had been filed Dr. Hoppin read the document carefully, and noticed that the Wurzburg diploma was literally the same as the Jefferson College diploma, except that where "Jeffersonianis" occurs in the Latin form "Wurzburgi" had been substituted. Such personages as a president, vice-president, and secretary appear on the Wurzburg diploma as officers of the German university. These points struck the registration clerk as decidedly peculiar; so he sent a request to Dr. P. D. Keyser, a graduate of a German university, to please call at the Prothonotary's office and examine the Wurzburg document. Dr. Keyser was convinced that the document was irregular, and it then occurred to him that Dr. Franklin D. Castle was a graduate of the Wurzburg University. So Dr. Castle's diploma was obtained, and the genuine was found to be altogether different from the one offered by Reinhardt. The clerk immediately notified Reinhardt to return the certificate issued to him.

Gentle Peace.—The editor of the Louisville *Medical Herald* has got married, and formally announces that he has abolished the war department of his journal.

Methods of Epilation.—Dr. C. Heitzmann recommends the introduction of caustic potash in solution of water, one to six, or one to four. This is to be introduced with a needle, and applications of cold cream used to allay pain and subsequent irritation.

The following depilatory pomade is given in *La Press Médicale*:

℞. Sodii carbon ..... ʒ j.
Quicklime ..... ʒ ss.
Charcoal powder ..... gr. viij.
Glycerine ..... f. ʒ j.
Lard ..... ʒ viij.
M.

After applying this to the affected parts for ten or twelve days, the skin takes a rose tint, and the hairs may be drawn out without pain.—*Medical and Surgical Reporter.*

Chicago as a Homœopathic Medical Centre.—The push and enthusiasm in other branches of business in Chicago has extended to the medical colleges. A third "allopathic" college is organized, and the two old ones vie with each other to excel in thoroughness. This healthy rivalry extends to the colleges of our own school. The Chicago Homœopathic Medical College is putting up a large building by the side of one of the largest hospitals in the country, as a rival of the largest "allopathic" college in the West. This is a bold move, and one that is arresting general attention. The time is not far distant when its faculty will form part of the staff of the great hospital. The rivalry in thoroughness and clinical facilities is certainly commendable. These features, with low fees, are powerful attractions to students. Chicago is rapidly assuming a front rank as a medical centre.—*U. S. Medical Investigator (Homœopathic).*

A New Method of Producing Local Anæsthesia.—Mr. Thomas Taylor, of the Agricultural Department at Washington, has devised a new freezing microtome, and upon the same principle a new method of applying a freezing mixture to the skin for the purpose of inducing local anæsthesia. The apparatus in both instances consists of a hollow metal cylinder, through which runs a spiral tube. The latter is connected by a tube with a vessel containing a freezing mixture of ice and salt, and bears at its opposite extremity an escape-pipe of smaller calibre. As the freezing mixture enters the cylinder, the fluid which results from the melting escapes through the escape-pipe, so that while in use the apparatus will always be a cylinder filled with a solid freezing mixture. According to Mr. Taylor, the tongue will cling to the apparatus and become anæsthetized in a few seconds. It seems that the ether-spray has had its days of usefulness.—*Cincinnati Lancet and Clinic.*

Ergot in the Treatment of Sea-Sickness.—Dr. T. S. Hopkins, of Thomasville, Ga., writes very enthusiastically in regard to the value of ergot for the relief of sea-sickness, from personal experience in a passage from Philadelphia to Savannah. He considers the following formula as preventive as well as curative:

℞. Ext. ergot fl. (Squibb's), f. ʒ ss.; potass. bromid., ʒ ss.; aquæ, ad. ʒ vj. M. Sig.—ʒ ss. two or three times a day.—*Medical News.*

Recent Philadelphia Appointments.—Dr. De Forrest Willard has been elected surgeon to the Presbyterian Hospital of Philadelphia, vice Dr. H. Lenox Hodge, deceased. Dr. Charles T. Hunter has been appointed Demonstrator of Anatomy, and Dr. J. William White, Demonstrator of Surgery in the University of Pennsylvania. Dr. William H. Parish has recently been elected Professor of Anatomy in the Woman's Medical College. Dr. Henry Leffmann has been elected active member of the Society of Public Analysts of England. The Philadelphia County Medical Society has established a section, or committee, on Clinical Pathology, of which Dr. John B. Roberts has been elected chairman, and Dr. W. H. Parish secretary. This is a new departure in Philadelphia, and seems to have been modelled after the New York Academy of Medicine. It is to be presumed that other sections will be established by the Philadelphia society, if that on Clinical Pathology proves successful.

State Board Examinations.—Of the fourteen applicants for certificates to practise medicine in Illinois, who recently appeared before the State Board of Health in Chicago for examination, all but two failed to pass. There is no longer a royal road to the medical profession in Illinois. The examination on materia medica was the one given at Harvard in 1880, and published in their last catalogue; that on jurisprudence was taken from Dartmouth. Examination was required on nine branches, including hygiene and medical jurisprudence.

Injection Brou.—The following is believed to be the formula of the much-vaunted gonorrhœal injection of this name, taken from the register in the French Public Office:

℞. Zinci sulph ..... gr. viij.
Plumbi acetat ..... gr. xv.
Tinct. catechu ..... ʒ ij.
Tinct. opii aqua ..... ʒ iij.
M.

Alumni Association of the Albany Medical College.—At a meeting of the Executive Committee of the Alumni, the president stated that he had given considerable attention to the matter of prize essays to increase the interest in, and efficiency of, the association. He had concluded to offer an

annual prize of $100, to be called "A Surgical Prize," and would announce as the subject for this year, "Essay on Colles's Fracture: its Pathology and Treatment," to be accompanied with a pathological specimen illustrating the fracture, with or without dislocation of the ulna, or a careful dissection of the hand, wrist, or forearm.

After favorable remarks by members of the committee, on motion of Dr. L. Hale, Dr. Van Derveer, the president, was appointed a committee of one to give the matter further consideration. Subsequently he reported that the heirs of the late Prof. Alden March, M.D., LL.D., desired to give the sum of $100 as an annual "March Memorial Prize," the essay for the coming year to be on the "Pathology and Treatment of Morbus Coxarius." Also, that Mr. McClure, a governor of the Albany Hospital, had decided to give the sum of $100 annually as an "Armsby Memorial Prize," the essay to be on some anatomical subject. That for the coming year will consist of a minute description of the "Genito-Urinary Organs of the Male," together with a carefully dissected specimen of the same.

The president further reported that the heirs of the late Prof. James MacNaughton, M.D., had offered the sum of $100 as a "MacNaughton Memorial Prize," the subject of the essay for the current year to be "Antisepsis in the Treatment of Diseases." And Mr. Joseph Russell, a trustee of the college, offers this year a second surgical prize of $50 for the second best essay on "Colles's Fracture."

Essays and specimens designated by a motto, and accompanied by a sealed envelope enclosed with the same motto, and containing the name and address of the author, must be sent to the Secretary, Dr. W. G. Tucker, by February 14, 1882. The committee to examine the essays for this year will consist of Drs. A. Van Derveer, J. S. Mosher, and Lorenzo Hale, and they reserve the right to reject any or all essays if not deemed worthy.

All specimens are to be deposited in the new museum of the college, properly labelled.

American Dermatological Association.—The fifth annual meeting of this association was held in Newport, R. I., on August 30th and 31st, and September 1st.

Albany College of Pharmacy—Department of Pharmacy of Union University.—The plan for the organization of such an institution has been recently perfected, and at a meeting of the Board of Governors of Union University, a department of pharmacy in the University, to be known as the "Albany College of Pharmacy," was created. With no similar institution nearer than New York, and but ten or a dozen such in the United States, it has frequently been impossible in the past, for those desirous of obtaining instruction in pharmacy, to secure the advantages offered by a collegiate course. Albany is practically the centre of a large portion of the State, and many of those who have heretofore been deterred from attendance upon a college of pharmacy may now, with comparative ease, obtain the advantages which such an institution offers.

The exercises of the college will be held in the Albany Medical College building, the lecture-rooms and laboratories of which are well adapted to its needs. The course of study is modelled upon those pursued in the leading colleges of pharmacy now in successful operation, and includes lectures, abundantly illustrated, upon botany, materia medica, and pharmacognosy, theoretical, general and pharmaceutical chemistry, and theoretical and practical pharmacy, together with practical laboratory exercises. The faculty will consist of the following members: Jacob S. Mosher, M.D., Professor of Botany and Materia Medica; Willis G. Tucker, M.D., Professor of Chemistry; Gustavus Michaelis, Professor of Pharmacy.

The course of instruction is graded, extending over two years, and divided into junior and senior classes, consisting respectively of first and second year students. Each course occupies five months, beginning the first Monday in October and closing about the first of March.

Small-Pox in Philadelphia.—The Philadelphia papers report a continued prevalence of small-pox in Philadelphia. Sixty-two new cases were reported in one week in September.

Death of Dr. Joel Pomeren.—Dr. Joel Pomeren, surgeon of President Garfield's regiment, and widely known throughout his State, died September 15th, at Millersburg, of disease contracted during the late war. He was fifty-six years old.

Another Victim to Yellow Fever.—Assistant Surgeon Green, of the U. S. Marine Hospital Service, died recently at Key West, Fla., of yellow fever. This is the second surgeon in that service who has died at Key West from the fever.

Prizes Worth Striving For.—The Royal Academy of Medicine of Brussels announces a prize to be awarded in January, 1884, of eight thousand francs ($1,600), for the best explanation of the pathology and therapeutics of the diseases of the nervous centres, especially epilepsy, illustrated by clinical data and experiments. If the essayist is successful in making a decided advance in the therapeutics of such diseases; if, for instance, he discovers a successful treatment for epilepsy—he is to receive, in addition to the sum above stated, a second sum of twenty-five thousand francs ($5,000). This money has been placed in the hands of the Academy by a person who does not wish his name to appear.

In Italy, the Academy of Medicine of Turin offers a prize of twenty thousand lire ($4,000) for the best essay on "The Physiopathology of the Blood." This is the Riberi Prize, and is open to the world, but the essay must be either in the Latin, French, or Italian tongue.—*Med. and Surgical Reporter.*

Peritoneal Transfusion of Blood.—This operation, recommended by Ponfick, and sustained by the experiments of Bizzozero and Colzi, was recently performed in Italy, with happy results. The patient was at the point of death from post-partum hemorrhage. Two hundred grammes of blood, drawn from a man, then defibrinated, and injected into the woman's peritoneal cavity, brought about a complete recovery.

Four Testicles.—The *Gaceta Medica Sevilla* mentions a curious case observed by Dr. Cebeira, in the San Fernando hospital. A soldier entered this institution to be treated for syphilis; on examination he was found to have four testicles, more or less involved in the disease, and enclosed in two perfectly normal scrota.

A Foreign Body in the Rectum.—The *Gazzetta Medica di Roma* states that a man, aged forty-eight years, in a fit of drunkenness introduced into his rectum a glass twenty-one centimetres in circumference and nine centimetres in length. Great caution

was necessary in the extraction of this voluminous and fragile body, pushed up, as it was, a considerable distance. The operation having been satisfactorily performed, the patient made a good recovery.

TRICHINÆ IN FISH.—The trichinæ are extending their dominion. At first they were only noticed in terrestrial animals. Now they are found in aquatic creatures. According to the *Goot Herait*, they were discovered in the body of a pike caught in the vicinity of Ostend. Professor Eleutin, of that city, who is much interested in the microscopical examination of fishes, found this one to be filled with trichinæ. Pikes are voracious, and in eating the remains of an animal affected with the parasite they may themselves become the victims of trichinosis, and be capable of transmitting the disease to persons partaking of their flesh.

DEATH FROM SPINAL CYST, UNRECOGNIZED.—Dr. J. Naylor Bradfield sends us the following case: Miss W——, a remarkably well-developed brunette, beginning menstruation at the age of fourteen, and always enjoying robust health, with perfect regularity in the catamenial function from the date of its commencement until near the middle of last September, at which time, and a few days preceding the usual period of her menstruation, she contracted a severe and persistent cold, followed by amenorrhœa, dull pains about the pelvis, and a sense of weariness upon the slightest exertion.

With the seat of greatest suffering located directly over the sacrum, pains shooting up the back, numbness of the lower extremities, nausea, and vomiting, augmented by the ingestion of almost every aliment, and the menses still in abeyance, Miss W. continued about the house until October 28th, when, with the pains in her back increased to a degree of unsupportable agony, and the nausea and vomiting unrelieved by scarcely a moment's rest, she was no longer able to quit her room, and on the evening of the above date took to her bed from sheer exhaustion, in part the result of her inability to receive sufficient nourishment, though in great measure depending on the excruciating pain, from which she had suffered unremittingly since the inception of what she expressed "a very bad cold," and which *cold* she believed was the probable cause of all her local distress.

Obviously deceived in his diagnosis, the physician from the first in attendance (and whom we may designate as Dr. X.) being asked to relinquish his care of the case, declared his opinion to be, that the suffering complained of was in great part imaginary, of really little account in the matter of prognosis, and that a week or two, at most, would certainly terminate the physical disturbance which the patient now bemoaned.

Finding, after the lapse of a few days, that, instead of the favorable issue so confidentially predicted, the patient in truth was surely and rapidly failing, the writer was summoned to see and take charge of the case, Wednesday evening, November 10th. I was scarcely able, upon reaching the bedside of the wretched girl—now wild and haggard with long-continued suffering—to believe her identical with the sprightly creature I had so long known and looked upon as a rare picture of vigorous health.

At the time of making my first visit to this unfortunate case, the suffering chiefly complained of was, as already stated, the sharp and ever-constant pain above the sacrum and across or through the hips, the patient actually writhing with the frightful torture, for which the usual remedies gave no respite or alleviation, the large doses of morphia relieving in a measure the nausea and vomiting, but imperceptibly, if at all, influencing the course or character of her local suffering, the marked peculiarity of the symptoms being a never-ceasing sense of unrest, or nervous agitation, which kept the patient constantly in motion, every instant fretfully changing her position from one place to another, evidently with the purpose of finding some possible spot or posture promising a momentary suspense in the desperate struggle, so rapidly outwearing the physical energies of her wretched existence.

Night and day, without a moment's ease or conscious rest from pain, the poor girl tossed and rolled upon her bed like one in the mortal pangs of a fatal poisoning, now throwing herself to one place, then writhing to another, or rolling to the edge of the bed and lashing the floor with her long black hair, and repeating piteously with almost every breath, "Oh my back, my back! my poor, poor back!" The unequal battle for life continued uninterruptedly, until Friday midnight, November 12 (fifty-four hours from the time of my first visit), when, without a diagnosis, or more than a mere conjecture as to the probable nature and seat of her disorder, death happily put an end to the intolerable strife for which we had found no anodyne or antidote in medicine.

As it had been intimated by some that the trouble was due to pregnancy and that the pains were those of abortion, at the request of the patient and friends, I had made a physical examination of the pelvic organs. The result showed, most happily, the patient's virginity, the uterus being small or imperfectly developed, the hymen a delicate, unruptured membrane, and not the slightest indication of any uterine trouble whatsoever.

Post-mortem by Drs. P. V. Hewlett, A. K. Baldwin, and the writer, made thirty-six hours after death, fully demonstrated the following facts: Pelvic organs entirely healthy (hymen intact and partially imperforate), right ovary containing partly matured ova. Right kidney sound, left one showing slight traces of fatty metamorphosis. Spleen, liver, pancreas, large and small intestine, together with all the thoracic organs, perfectly free from disease. Mucous membrane of the stomach inflamed over a large portion of its posterior wall, and two deep ulcers, the one nearly healed, the other in active operation at the time of the patient's death, were found within an inch of each other, near the centre of the inflammatory patch.

Nowhere along or in close proximity to the spinal column could there be seen, felt, or from any external signs suspected, the presence of spinal disease, the most decided pressure, sharp raps, and various contortions of the body producing in life no further increase of pain.

Believing the gastritis to explain satisfactorily the nausea and vomiting, the important problem next to unravel was the source and cause of the incorrigible suffering, from which the patient had certainly succumbed—a pathological proposition for which the post-mortem had thus far suggested no possible solution. When again and haply referring a second time to the affected kidney, a distinctly marked fulness, or puffing out of the tissues was seen to occupy the space directly behind and for some distance below the normal position of the affected (left) kidney, though apparently unconnected with or referable to its morbid condition, the walls of the cyst being exceedingly delicate, and rupturing upon

slight pressure, with the discharge of two or three ounces of a bloody sero-purulent fluid.

The cyst-cavity would have received an ordinary size goose-egg, and lay directly alongside the vertebral column, in two or three places dissecting up the periosteum, and exposing small plates of denuded bone. The cord itself seemed perfectly healthy, the meninges, however, being slightly congested, and showing patches of inflammatory deposit at a point directly underlying or contiguous to the posterior cyst-wall.

Whatever the origin of the spinal cyst was it is impossible to say.

Without the necessary time for even a partial review of the literature including such cases as the one above reported, it is, if the writer correctly remembers, recorded as a fact by most authors that to exactly fix upon the seat of morbid action in many cases of spinal disease is a matter generally as difficult as experienced in the case of our own unfortunate patient, the negative rather than the positive symptoms being, so to speak, our chief or diagnostic guide in locating spinal disease. Thus Dr. Hilton, in his recent work on "Rest and Pain," writes: "In disease of the spine there is one symptom which almost always stands out most prominently, I might almost say, solicits our right appreciation of it, and that is, local and fixed pain upon the surface of the body, with or without exacerbations, local increase of temperature being absent at this spot. I feel quite certain that, through the medium of this symptom, properly employed, we may be led to the recognition of morbid conditions of the spine long before there is any evidence of disease by palpable deformity."

Causation of the First Heart-Sound.—In a recent memoir, published in the *Tribune Médicale*, Dr. Rosolimos objects to the current theories in regard to the origin of the first sound of the heart. According to the author, its cause is a vibration of the chordæ tendinæ alone, provoked in systole by the movement of the blood through the net-work formed by these cords. He bases his assertions upon experimental researches.

Cocoa a Cure for Morphinism.—*La Independencia Medico* quotes the following case: A lady had been in the habit of alleviating her sufferings with morphine, of which drug she finally took sixteen grains a day. Thirty hours after having taken her last dose, she was found in a condition of great anguish, excitation, and inquietude. During the night chloral hydrate and iodide of potassium were given to allay the excitation and produce sleep. The next day she was very weak and restless, hardly able to speak, and tormented with vomiting; the pulse was 150. The fluid extract of cocoa was administered in doses of a tablespoonful. The first dose had but little effect. The second was followed by a wonderful change; the pulse fell to 85, the countenance assumed color and animation, and the vomiting ceased. The patient began to speak, and was in excellent spirits. She slept almost the half of the following night, awoke refreshed, with a pulse of 75, took breakfast, and digested it well. She continued to improve, rode in a carriage for quite a distance, and left the city next day, taking with her an eight-ounce bottle of cocoa, which remedy she continued to take in diminishing quantities. When she ceased taking it she was enjoying good health, without the use of morphine.

A Remedy for Intermittent Fevers.—Dr. Bruneti recommends, as an efficacious remedy in intermittent fevers, a preparation composed of twelve grammes of the chloride of sodium and one gramme of ferric carbonate. This is to be divided into six doses, to be taken in twenty-four hours. To prevent the recurrence of the malady, one dose a day is to be taken for the following week.

A Resurrection.—Bucharest papers relate the following incident: A young woman died of small-pox, and, pursuant to police regulations in times of epidemics, the body was interred without loss of time. The girl had been engaged to be married, and, accordingly, her relatives had adorned the body of the deceased with the jewels that had been presented to her. These trinkets aroused the cupidity of three individuals, who resolved to desecrate the tomb. The grave was opened, the body taken out, and the jewels removed. During these procedures one of the robbers was, by his companions, accused of cowardice, and to disprove the assertion he launched a terrible blow at the dead girl. The effect was magical; the supposed corpse assumed the sitting posture and begged for mercy; the robbers, however, fled terror-stricken in hot haste. The girl arose and with trembling steps sought the dwelling-place of the curate, who, after a preliminary scare, finally comprehended the situation, and volunteered to prepare her relations for the news. Joy reigned supreme. In consideration of the service they had rendered the robbers were not prosecuted.

A Natural Collodion.—Sr. Filiquier has extracted the fluid found in the gall-nuts adherent to the branches of the ulmus campestris. On several occasions he had made use of the agglutinating properties of this liquid to unite the edges of wounds produced by cutting instruments. The results obtained are identical with those of the officinal collodion.

Hemeralopia in Hepatic Diseases.—In an article upon the above subject, published in the *Archives Générales de Médecine* (April, 1881), Dr. Parinaud makes the following statements:

"Day-vision is a complication of hepatic diseases which is not very rare. It manifests itself by a crisis of variable duration, being influenced by determinate accessory causes. It is seen in chronic affections especially, and particularly in cirrhosis, and appears after the organ has been for some time the seat of the disease. It does not appear to be produced by icterus, but by a peculiar alteration of the blood resulting from derangement of the hepatic function. It is of grave significance. It is probable that in the so-called essential hemeralopia, as well as in hepatic affections, the ocular trouble depends upon blood changes different from those of ordinary anæmia, these changes manifesting themselves in the organ of sight, modifying the secretion of visual purple.

A Splendid Opening for an Enterprising Physician.—According to the *Eco del Comercio*, the legislature of the State of Vera Cruz offers a prize of $100,000 to him who shall present a true antidote for all kinds of vomiting.

Rhodes' Audiphone.—Rhodes exhibited his instrument before the authorities of the National Institution for Deaf-Mutes, at Paris. Prof. Theobald and other deaf-mutes declared that the instrument was of no use whatever.

## REPORT OF THE

## CASE OF PRESIDENT GARFIELD,

### Accompanied with a Detailed Account of the Autopsy.

By D. W. BLISS, M.D.,

Washington, D. C., surgeon in charge of the case.

(*With Illustrations.*)

The great interest which has been manifested by the medical public in the surgical history of the case of President Garfield, and my close and direct connection with it as surgeon in charge, from the time I was summoned until his death, imposes upon me the obligation of giving, even at this early date, a general summary of the salient points connected with its diagnosis, treatment, and pathology.

It seems important at this time, in view of an implied demand on the part of my professional brethren throughout the country, that, at the risk of anticipating the complete and technical report, which will appear in due time under the editorial direction of J. J. Woodward, Surgeon U.S.A., and signed by all the gentlemen associated with me, that I should present such data as may serve to give the leading facts of the general plan of management of the case, the reasons for making the diagnosis, and such other points as were developed in its study which may serve to explain the most important autopsical lesions, the report of which accompanies this paper.

Perhaps these conditions can be fulfilled in no better way than by a summary in which the main and important data are given in the form of a general medical history. It is, perhaps, unnecessary to state at this point that I shall not undertake to reproduce the daily bulletins, nor a minute history of the dietetics, as they are not necessary to enable the profession to comprehend the general treatment as applied to the case in view of the erroneous diagnosis made, or to the conditions presented by the autopsy.

Immediately after the shooting of President Garfield, on the morning of July 2d, I was summoned by the Secretary of War to take charge of the case. I was conducted to an upper room in the building, where I found the President lying upon a mattress, in a semiprone position, on the left side. He presented the appearance of perfect collapse, the lines of expression were lost, there was extreme pallor, sighing respiration (about eight or ten per minute); pulse exceedingly small, feeble, and frequent, and ranging about 120. The ingesta lying upon the mattress indicated that he had recently vomited, and upon mentioning the fact the President replied that he had not; but assurances from the physicians and others, with the evidences before me, indicated that the emesis had taken place while he was unconscious. Large beads of perspiration stood upon his face, forehead, hands, and forearms.

There were present at that time Dr. Smith Townsend, the Health Officer of the District, and Dr. Purvis. The former, who was the first physician to reach the wounded President, informed me that he had administered half an ounce of brandy and a drachm of aromatic spirits of ammonia internally. The President's coat had previously been removed; the remainder of his clothing was intact, except that over the region of the wound, which was so arranged as to expose the point of entrance of the ball.

The President complained of a sense of weight and numbness, and subsequently of a tingling sensation and pain in the lower extremities. With a view of exploring the wound to ascertain the course of the ball and the organs involved in its passage, I introduced a Nélaton probe, which took a direction downward and forward, on a line which would represent a point of exit four inches to the right, and nearly directly opposite to the umbilicus. The point of entrance of the ball, which was oval and sharply cut, was on the right side, four inches from the median line of the spine, and on a line with the eleventh rib. A slight discharge of blood was oozing from this orifice, and had soiled the clothing. I passed the probe in the direction previously indicated, through the tenth intercostal space, for a distance of three and one-half inches from the surface of the body, to what appeared to be a cavity, and I was unable to detect any foreign substance beyond the rib to indicate the presence of fragments of bone or the missile. In attempting to withdraw the probe it became engaged between the fractured fragments and the end of the rib, and could not be liberated until pressure was made upon the sternal end of the rib so as to slightly elevate its fractured extremity. I then passed the little finger of my left hand to its full extent into the wound, which developed the character and extent of the fracture of the rib, and was only able to reach a point on a line with the inner surface of the rib, where it came in contact with what appeared to be lacerated tissue or comparatively firm coagula, probably the latter. After withdrawing my finger I made an exploration with a long, flexible silver probe, which I suitably curved before entering, and gently passed it downward and forward, and downward and backward in several directions, with a view of indicating the course of the ball, if it had been deflected by contact with the rib, and meeting with resistance from soft parts I desisted and excluded the probability of deflection, being inclined to the opinion that the ball had entered the liver, which, if true, would not warrant further exploration in that direction.

By this time a large number of physicians had gathered in the room, and I gave to them a hurried account of my examination, and expressed the opinion that no further explorations should be made during the stage of collapse, and that stimulants by the stomach should not at that time be given, as the President was suffering from constant nausea, and in his condition of collapse absorption would not take place, and further that they would become a source of additional irritation. In these opinions, expressed at the council in one corner of the room, the physicians concurred. The gentlemen in attendance at this time, so far as I can recollect, were Drs. Townshend, Purvis, Reyburn, Norris, Lincoln, and Ford.

The President repeatedly requested that he be taken to the White House, and after further consultation and a full understanding of the manner and detail of his transfer, his speedy removal was agreed upon. Temporary dressings were applied to the wound, when the President was lifted on to the mattress, carefully placed upon a stretcher, conveyed down-stairs, and placed in an ambulance in waiting. The vehicle was driven with great care over the

rough pavement of Sixth street, about forty yards' distance, until reaching the smooth asphalt pavement of Pennsylvania avenue. The great rush of people, in the excitement, made it necessary to move rapidly. On the way there was no disagreeable motion in the carriage, which fact is attested by Dr. Townshend and others who accompanied me in the ambulance. On inquiry, the President replied that the motions of the carriage did not give him any discomfort. At the street railroad crossings at Seventh and Fourteenth streets, the vehicle was driven with exceeding caution, and with scarcely an uncomfortable motion. He was then taken in the same manner as before to his room, and placed with extreme caution on the low family bed. The room is known as the southwest or family room of the house. On his arrival thither a careful examination was made of his condition. The pulse continued feeble, frequent, and extremely compressible; the respiration was slow and sighing; extremities and surface cold, with occasional vomiting and profuse perspiration over the entire body; voice husky, with constant complaint of severe pains in the inferior extremities. He was placed upon his right side, so as to make the wound dependent, to facilitate drainage, and keep the viscera in contact with the injured parietes, with a view of preventing further hemorrhage and looking to the possible adhesion of the injured parts to the peritoneum. After consultation it was deemed improper to remove the clothing, as such a proceeding would thus increase the dangers. Water was given in small quantities, often repeated. This was necessitated by the extreme thirst from which the patient suffered.

A hypodermic injection of one-eighth of a grain of morphine and one-eightieth grain of atropia was administered to control the pain in the extremities, and as a more permanent stimulant to assist reaction. The place selected for injection was the dorsal aspect of the forearm. This was about 10 A.M., July 2d.

There was but little change in the condition of the patient, either in temperature, respiration, or pulse, until about 11 o'clock, when it was determined to repeat the morphine in the dose of one-sixth of a grain, the atropia being omitted. This soon had the effect of modifying the pain and discomfort, and the respiration became more frequent and easy. The pulse responded but little to the stimulants. Nausea and vomiting continued at intervals of thirty minutes during the entire day and until 7 P.M., when it became less frequent, with less retching—in fact, being simply a regurgitation of the fluids of the stomach. This condition continued at longer intervals until 6 o'clock the following morning.

At 5.30 P.M., in accordance with a previous understanding with the physicians, the clothing was removed by being cut from the body in such a manner as to prevent any motion or agitation, and to permit the more successful application of dry heat by warm flannels to the entire body, which had been imperfectly accomplished before. Upon examination, a well-defined field of dulness over the region of the wound, thought to be due to hemorrhage in the substance of the liver, along the supposed track of the ball, extended seven and one-half inches anteroposteriorly and five and one-half inches laterally.

The urine was retained until 6 o'clock P.M., when a flexible, velvet-eyed catheter was introduced, and about six ounces of normal urine drawn. During the remainder of his illness the urine was voided without restraint, and frequent careful examinations were made, proving the absence of albumen or other significant abnormal ingredients. A spontaneous evacuation of the bowels took place on July 3d, which was natural in character and free from blood or other foreign matter. After this, and during the entire period of his illness, the President was not subject to diarrhœa, and his movements were either spontaneous or regulated by enemata. The only exception to this was that during the last few days of his illness, occasional small involuntary evacuations took place, which seemed to depend upon the existence of large hemorrhoids, which, from their size and locality, produced dilatation and partial paralysis of the sphincter muscle, the evacuation always occurring in an effort to expel flatus.

At 10 P.M. the pulse was 158, temperature 96.5°, respiration 35, which was the most critical period attending the collapse. At 11.20 P.M. the evidences of reaction began to manifest themselves.

When the pulse had diminished to 120, the temperature had risen to 98° F., and the respiration was 18. The carbolized absorbent cotton which had previously sealed the wound having become displaced, was reapplied.

Until 2 P.M. of July 3d, the variations of pulse were comparatively slight, ranging from 104 to 120, the respiration being normal.

The patient slept at short intervals, generally arousing with an effort at regurgitation of the contents of the stomach, but otherwise expressed a feeling of comfort and gave evidences of rest. During the night he seemed to be refreshed and was comparatively free from pain. There was no time after my first visit, up to this period, that the patient was not perfectly rational, and often made brief, pertinent inquiries as to the character of the wound and his condition.

At the evening consultation, July 2d (7 P.M.), the opinion was expressed by some of the medical gentlemen invited to the case, that internal hemorrhage had taken place, and that he would not survive the night, and expressed these views to the council. The symptoms of profound collapse were so grave that Surgeon-General Wales was induced to express the opinion that the President was dying.

The consultations heretofore referred to were, as a matter of course, held in the adjoining room. Only three or four physicians of the number present were invited to visit the bedside on each occasion to make personal examinations, to verify the reported progress, and enable them to intelligently advise the council.

The gentlemen invited by me to visit the bedside were Surgeon-General Wales, Surgeon J. J. Woodward, and Dr. Reyburn. On that occasion the opinion was expressed that the field of dulness heretofore referred to, the boundaries of which were well defined, was thought to be due to hemorrhage in the substance of the liver, from the passage of the ball into or through it. The opinion obtained, and was so expressed to the council, that internal hemorrhage was then taking place, and that the extreme prostration and feebleness of the respiration were due to that cause, and that the President would not survive the night.

There was some oozing of dark venous blood during the entire night, sufficient to saturate the carbolized cotton and stain the bed. On the following morning the hemorrhage had entirely ceased, and the dressings became adherent to the skin.

All the physicians visited the White House at 8 A.M., July 3d, for the morning consultation, agreeably to a previous understanding that such should be the case if the President survive the night.

At this consultation, Surgeon-General Barnes and Surgeon Woodward, U.S.A., Dr. Reyburn and Dr. N. S. Lincoln, visited the bedside of the patient with me, with a view of making the necessary examinations, dressing the wound, and of reporting results to the other members of the council. The patient was found with a pulse of 115; the temperature was nearly normal, as was the respiration. He was cheerful, gave evidence of being rested, and made definite inquiries regarding his condition and prospects. The use of morphine hypodermically, in doses of sufficient quantities to control the pain in the extremities, was advised, and it was agreed that the patient should, continue to occupy the position on his right side as before directed, so far as was possible; and that the wound should be exposed only when the dressings became disarranged; and that their character should not be changed.

Immediately after the consultation, the subject of medical attendance was considered by the President. The only persons present were, besides the President, Mrs. Garfield and myself. He then formally placed himself under my professional care, and requested me to select my counsel, the result of which is well known. He also desired me to individually thank the large number of physicians who had composed the council up to that time, which I accordingly did.

The primary reaction reached its highest point of temperature, pulse, and respiration, at 2 P.M. on Sunday, July 3d. Slight tympanites was detected, but no pain on pressure, nor any marked rigidity of the abdominal walls. These were the only symptoms which pointed to the existence of peritonitis throughout the whole course of the case, and the spontaneous movement of the bowels, already noted, was an additional evidence that the peritoneum was not involved.

At 10.45 P.M. the pulse had gradually increased in frequency until it reached 120. The temperature remained at 100°, and respiration at 20. At this time Dr. D. Hayes Agnew, of Philadelphia, and Dr. Frank H. Hamilton, of New York, were summoned to visit the patient in consultation. Dr. Agnew arrived about 4 o'clock the following morning, July 4th, and Dr. Hamilton at 6 A.M. They were presented to the President formally at the consultation, 8.15 A.M., July 4th, at which time the pulse was 104, temperature 99.4°, and respiration 19. He had passed a comparatively comfortable night, awakening every twenty or thirty minutes, taking water or liquid nourishment in small quantities each time, and dropping quickly to rest. The nausea had quite subsided, and the pain and soreness of the lower extremities was measurably controlled by the administration of morphia, which was continued in quarter-grain doses each evening, administered hypodermically.

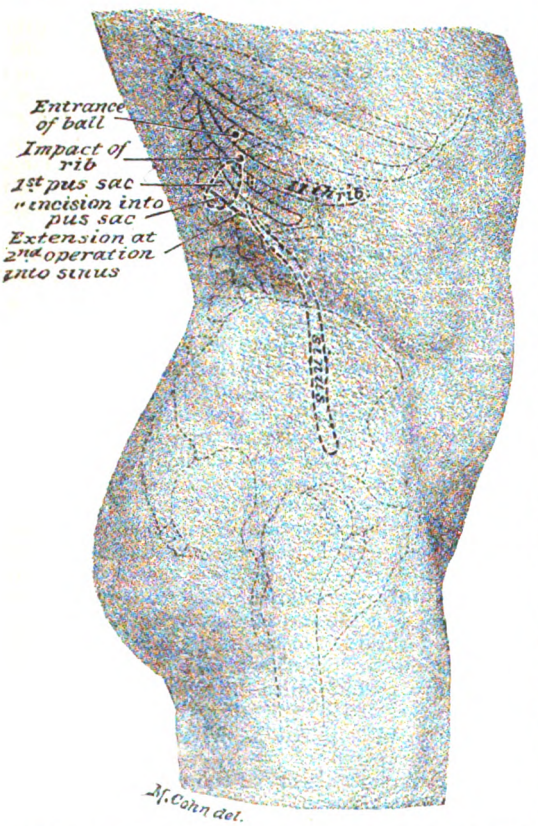
A careful review of the case from the time I first saw the President was given to these gentlemen, with the request that they, with the data before them, examine the case thoroughly, as though it was their own, and freely express their views of the character and gravity of the injury and the course of treatment of the case up to that time. I also gave them a detailed account of the explorations made in the wound, and the unsettled convictions as then held as to the course of the missile and the organs involved in the injury. They individually examined the wound with great care. These examinations consisted in the introduction, in different directions, of probes, flexible bougies, in order, if possible, to determine the course of the ball. With the evidences developed by this personal examination, together with the complete history of the shooting of the President, and the progress of the symptoms for the first forty-seven hours, they proceeded to discuss the possible course of the ball and organs involved, viz., whether it passed directly forward into or through the liver, or was deflected backward at a right angle so as to involve the spinal column, or downward behind the peritoneum toward the pelvic cavity. Carefully weighing all the evidences, the more prominent symptoms upon which the diagnosis was based are presented in the following order: The relative position of the assassin to the President at the time of the shooting, the direction of the ball through the tissues, so far as safe exploration could determine, gradual subsidence or modification of pain and hyperæsthesia of the feet and scrotum; the repeated unsuccessful efforts to pass a probe or flexible instrument more than one-half inch in any direction beyond the fractured rib, except in a direction downward, a little forward and anterior to the twelfth rib, a distance of about two inches. The fact also was considered that explorations had twice been made with the finger—one by myself soon after I reached the injured President, and subsequently by Surgeon-General Wales of the navy, on the occasion of the consultation on the evening of July 2d; and in each instance it was found impossible to successfully explore by that means beyond the inner border of the fractured rib so as to determine, with accuracy, the course of the ball, or even the condition of the tissues indicated by the end of the finger. Nor did they underestimate the significance of the profound shock, nor the unusual period of collapse which followed and seemed to point to extensive lesion of important viscera. However, that the kidneys, intestine, and peritoneum were not immediately involved, was made patent by the unrestrained passage of normal urine at proper intervals, the spontaneous movement from the bowels of natural fæces, the frequent discharge of flatus, and the absence of other symptoms of peritonitis. With all these facts before them it was impossible to determine positively the course taken by the ball. The indications pointed to a downward course of the ball into the pelvic cavity. Upon careful consideration of the foregoing facts and of the opinions expressed by the distinguished counsel, we were inclined to recede from the opinion at first adopted regarding the supposed passage of the ball through the liver. The propriety of making extensive incisions and dissections so as to explore the fractured ribs and remove as much as might be necessary to reveal the true course of the ball, was duly considered. But the opinion was maintained that the favorable progress of the President thus far did not warrant any interference, and, further, such an operation would seriously complicate the case and diminish the prospects of recovery. The facts revealed by the autopsy confirms the wisdom of the course pursued. With this view all the surgeons concurred.

The subsequent history of the case, which proved that the liver, kidneys, the intestines and the large vessels had escaped serious injury, as well as the gradual subsidence of the nervous disturbance of the lower extremities, the almost entire absence of pain in the back or that portion of the body in which the track existed, together with a pus-sac which dissected its course down behind the peritoneum into the right iliac fossa, was but corroborative, and naturally misled our judgments into an erroneous diagnosis.

On the evening of July 4th, the pain, hyperæsthesia, and vomiting had nearly disappeared, soreness of the feet supervening and continuing for some days.

The case progressed, with slight fluctuations, up to July 23d, when a rigor occurred at 7 P.M., followed by a pulse of 124, respiration 26, and temperature 104° F. Two days previous to this a pus-sac was observed in the common integument, extending down below the twelfth rib toward the erector spinæ muscle, and underneath the latissimus dorsi, and was carefully evacuated by gentle pressure into the original opening on the occasion of each dressing. We did not feel satisfied that this superficial and limited collection of pus, which was so readily evacuated, was the principal cause of the aggravation of the symptoms present. However, a free incision was made into the pus-sac, which afforded a more direct and dependent channel to the fractured rib, from which a small fragment of bone was removed.

Pressure made backward and upward upon the abdominal wall, between the umbilicus and anterior spine, gave exit to a flow of peculiarly white and firm pus. I remarked at the time to the council that the appearance of this pus gave assurance that it had never been exposed to the air, and must have come from a deep-seated source.



After this operation the improvement was not as prompt as we had reason to expect, and on the 26th of July the opening between the fractured ends of the eleventh rib was enlarged, and a small detached portion was removed. This facilitated the discharge of pus, and, as a result, a more uniform condition of the symptoms were maintained until about August 6th, when slight febrile exacerbations were observed, which continued to be manifest until the operation was made to afford a more free passage of pus from the supposed track of the ball. The necessity of the operation was more plainly developed by passing a flexible catheter through the opening previously made, which readily coursed toward the crest of the ilium, a distance of about seven inches. This cavity was evacuated twice daily, by passing through the catheter, previously inserted in the track, an aqueous solution of permanganate of potash from a small hand-fountain, slightly elevated, the water and pus returning and escaping at the opening externally. The indications for making a point of exit in the dependent portion of this pus-sac were urgent, and on August 8th the operation was performed by extending the incision previously made, downward and forward through the skin, subcutaneous fascia, external and internal oblique muscles, to a sinus or pus-channel. The exposed muscle contained a considerable number of minute spiculæ of bone. Upon carrying a long, curved director through the opening between the fractured rib downward to the point of incision, there was a deeper channel which had not been exposed by the operation thus far, and the incision was carried through the transversalis muscle and transversalis fascia, opening into the deeper track and exposing the end of the director. A catheter was then passed into the portion of the track below the incision, a distance of three and one-half inches, and in a direction near the anterior superior spinous process of the ilium. The President was etherized during this operation.

A comparatively uniform condition of temperature, pulse, and respiration continued until August 14th, when nausea, vomiting, and general prostration occurred, with an increase of pulse to 108, temperature 100.8° F., and respiration 19—the pulse continuing to increase, although the temperature remained nearly normal up to August 17th, when food was again retained by the stomach. When the previous attack of vomiting took place, August 14th, the stomach was placed at physiological rest, and resort was had to rectal alimentation until August 17th, when the function of the stomach was gradually reestablished and the enemata discontinued.

On August 18th a slight tumefaction of the right parotid gland was noticeable, unaccompanied by pain or tenderness on pressure, until the suppurative period was established, when mental disturbance, vomiting, restlessness, and jactitation supervened; nor was there any increase of temperature, local or systemic, to indicate the probability of its metastatic origin. The parotitis presented many of the characteristics of an ordinary carbuncle, and was unaccompanied by any other abscesses in the adjoining tissue. During the progress of the parotitis facial paralysis occurred, and continued, with slight improvement, until the time of his death. When the climax of suppuration was reached, a free discharge of laudable pus followed, with a rapid abatement of the more urgent symptoms, and after the separation of the slough (which was limited in extent) reparation was rapid and complete throughout the entire suppurating surface, as well as in the several incisions which had been previously made to liberate the pus. These lesions had entirely healed at the time of death, except an opening behind and below the right ear, referred to in the autopsy.

It was a marked feature during this whole period of parotid suppuration, that there was no associate systemic disturbance. The question of malarial complication was discussed at this time, but it must be

remembered that quinine had been given in tonic doses much of the time; and occasionally, when periodicity was noticeable, sedative doses were administered for a period of twenty-four hours at a time.

On August 19th a small slough was discharged from the lower pus-track, when the flexible catheter was readily passed downward a distance of twelve inches toward the right iliac fossa. This channel was kept free from accumulations by passing into it carbolic or permanganate water from the hand-fountain heretofore described, at the same time carefully withdrawing the catheter, so as to avoid undue distention of the track.

During the latter part of August a number of pustules of suppurating acne appeared in the axillæ, and later, four or five on the surface of the body. They were superficial, numbering five or six in each axilla, and about the size of large peas; they were opened as soon as suppuration took place, healed without recurrence, and are believed to have been due to the septic condition of the system. The small carbuncle mentioned in the report of the autopsy was doubtless referrable to the same cause. The above were the only suppurating surfaces, excepting the incisions made into the wound, and four small superficial bedsores formed on the sacrum, which were observed during the President's illness.

The subject of the removal of the President to a more salubrious locality had been discussed for several days, and was urgently presented at the consultation on August 25th. The majority of the council, with myself, considered that his removal at this time would be attended with very great hazard. The hope, however, was expressed that the President might be sustained until suppuration was established in the parotid, and the constitutional disturbances incident thereto had subsided, when it would be possible to remove him. Stimulants were given in doses of ʒ vj. with ʒ ij. of beef-tea, occasionally introducing ʒ j. of beef peptones, alternated with the yolk of an egg. These measures undoubtedly contributed largely to his sustention during this period of continued gastric disturbance.

Our efforts were rewarded on August 26th by a free discharge of pus from the external auditory canal; also in the mouth. It was believed that the pus which discharged in the mouth dissected its way along the course of Steno's duct. There being rigidity of the masseter muscle, the jaw was fixed so as to preclude the possibility of opening the mouth sufficiently for a satisfactory examination. A tenacious mucus was secreted from that side in large quantities, and occasioned great annoyance. The patient during this period was occasionally wandering in his mind, especially after rousing from sleep. When his attention was fixed by an attendant, his mental condition seemed to be comparatively perfect.

An interesting fact connected with the inflammation of the mucous membrane of the mouth was that it extended by continuity to the pharynx, larynx, trachea, and bronchi. The physical signs developed the fact that acute bronchial catarrh was the sequel. Hypostatic congestion of the lungs was observed for some weeks before, more extensive on the right than the left, because of decubitus. On the right side it extended to the sixth rib posteriorly, while on the left side it was comparatively slight. An improved condition was maintained with a free-suppurating condition of the parotid and marked reduction of the tumefaction of the gland.

Finally it was decided by the majority of the surgeons that the President should be removed to the sea-shore. The details as to the precautions taken to secure a safe transit were minute in every particular, and every provision was made to meet any emergency that might arise in the course of the journey—even preparations for his removal from the train to suitable places on the road had been previously selected, in case evidences of exhaustion should become manifest.

His transfer from the Executive Mansion to the cars was made with the least possible disturbance, without accident, and with perfect satisfaction and comfort to the patient. During the journey his pulse and temperature were taken from time to time, and frequent examinations made to determine the effect of the motion at different rates of speed. The minimum of unpleasant motion seemed to be secured at a rate of about sixty miles an hour. During the last hour of his journey he showed symptoms of fatigue, which would have prevented a longer journey, had such been required to reach his destination. His pulse increased, the countenance became slightly anxious, and the temperature measurably exalted at the period to which I allude.

He was transferred from the cars to the Elberon cottage without accident, the pulse at 10 P.M. reaching 124, temperature 101.6°. The morning of September 7th his pulse had fallen to 106, temperature 98.4°, respiration 18. The President expressed great satisfaction that he had arrived at the sea-shore, and, notwithstanding the heat of the two succeeding days, it made but little impression upon the distinguished patient, the pulse, temperature, and respiration continuing the same until September 15th, when his pulse slightly increased in the evening, so that it occasionally reached 120 during the night.

After his arrival at Elberon there was an extension of the bronchial catarrh into the ramifications of the bronchi of the right lung, and limited broncho-pneumonia followed.

I should mention here a fact well known, that the President was so much pleased with his improvement that he expressed that the number of his professional attendants should be reduced. Accordingly Drs. Barnes, Woodward, and Reyburn retired from the case, leaving Elberon the morning of September 8th.

September 17th, at 11 A.M., a severe rigor occurred of half an hour's duration, followed by a sharp rise in temperature. At 12 M. the pulse was 120, temperature 102° F., and respiration 24. The mental disturbances were more noticeable during the febrile rise, but the stomach was able to retain the nourishment and stimulants, which were given at regular intervals in the form of milk-punch. This chill was accompanied by severe pain over the anterior mediastinum, and the President said to me that it was similar to what he understood as angina pectoris. It is evident that this pain, which occurred on several occasions at intervals of six to twelve hours prior to his death, was occasioned by first a rupture of the aneurismal sac, and the progressive dissection, at irregular intervals, of the blood into the surrounding tissue, until finally it burst into the peritoneum.

A febrile rise was very marked by twelve noon of the 17th, attended with great anxiety of countenance, the temperature falling to 98° F., the lowest point of normal range, the pulse being, however, steadily at 102, and rather feeble. While there was, in my judgment, an absence of typical metastatic abscesses to produce this symptom, there was a profound expression of gravity in his condition that was not

commensurate with the systemic disturbance, and which prevented my absence, even for a few moments at a time. I remarked to Dr. Agnew: "I am in constant fear of some danger impending. We may have a terrible outburst, possibly in the shape of a cardiac thrombus." I said to members of the family: "There is a gravity in this case that portends serious trouble."

At 6 P. M. of the 18th there was another chill, accompanied with pain as before. The febrile rise continued until midnight, the pulse varying from 112 to 130.

At 8 A. M., September 19th, the pulse was 106 and feeble; temperature, 108 8°, and all the conditions unfavorable. In half an hour afterward there was still another chill, followed by febrile rise and sweating, and also with pain as before. During the periods of chill and fever he was more or less unconscious. He passed all day in comparative comfort, and at 8.30 in the evening his pulse was 108, respiration 20, and temperature evidently a little lower than normal.

At 10.10 P.M. I was summoned hastily to the bedside, and found the President in an unconscious and dying condition, pulseless at the wrist, with extreme pallor, the eyes opened and turned upward, and respiration eight per minute, and gasping. Placing my finger upon the carotid, I could not recognize pulsation; applying my ear over the heart, I detected an indistinct flutter, which continued until 10.35, when he expired. The brave and heroic sufferer, the nation's patient, for whom all had labored so cheerfully and unceasingly, had passed away.

Soon after the President expired, it became necessary to make arrangements for an autopsy, so as to present to the profession, in a definite manner, the track of the ball and the parts involved; also to ascertain the immediate cause of death. I deemed it proper to invite Surgeon-General Barnes, and Surgeon J. J. Woodward, U.S.A., and Dr. Robert Reyburn, of Washington, D. C., who were formerly associated in the case, to take part in the autopsy, and also invited, at the instance of Dr. Woodward, Dr. Lamb, of the Army Medical Museum, for the same purpose. The former gentlemen arrived at Elberon, N. J., about 3.45 P.M., when the post-mortem examination was commenced. Dr. A. H. Smith, of New Jersey and New York, and temporarily at Elberon, was also invited.

The most important points revealed by the autopsy, and which are to be considered by the profession, are:

*First.*—Would the condition of the President, immediately after his injury, have justified a more thorough exploration of the wound, or would such a procedure have been safe at any time before primary reaction was established?

*Second.*—Was his transfer to the executive mansion timely and properly made?

*Third.*—Were the best and most judicious means instituted to secure prompt reaction?

*Fourth.*—After reaction was comparatively complete on the 3d of July, and when there had occurred spontaneous evacuations of normal urine and alvine evacuations, and an absence of any evidence of internal hemorrhage or peritonitis, would further exploration have been necessary, especially when it is considered that the probable reopening of the lacerated vessels would induce hemorrhage?

*Fifth.*—Were the surgeons then in attendance justified in deferring any further exploration until the arrival of the distinguished counsel on the morning of July 4th?

*Sixth.*—At the consultation, July 4th, and after it was proved to be impossible to follow the track of the ball any considerable distance beyond the fractured rib, would an operation have been justifiable, necessitating an incision through the soft parts and a removal of a portion of the rib, so as to develop the track.

*Seventh.*—In the light of modern military surgery, which teaches the readiness with which leaden balls become encysted, would an operation at any time for removal of the missile have been justified unless there was some evidence of the missile being a source of irritation?

*Eighth.*—Considering carefully the condition of the President during the entire period of his illness, and the facts revealed by the autopsy, would not any operation for the purposes before mentioned have placed the President's life in great jeopardy, and, at best, have hastened the time of his death, without affording any signal relief?

*Ninth.*—Was the treatment of the case as presented proper, and did it or not prolong his life to the utmost limit?

*Tenth.*—Was the mistaken diagnosis a natural result of the conditions present, and to have developed a correct diagnosis would not operative procedures have ensued?

*Eleventh.*—If we had known the exact course and locality of the ball, and the organs injured in its passage, should the treatment have been modified in any particular?

The artistic drawings which accompany this history will, I trust, facilitate its study, and their accuracy is attested not only by myself, but by Prof. Faneuil D. Weisse, M.D., and Dr. Geo. F. Shrady, of New York, both of whom visited Washington, on my invitation, to study the case, and make thorough and personal examination of the specimens preserved, with a view of verifying the facts in its history.

These drawings were made by Mr. Max Cohn, of New York, who came to Washington, D. C., for that purpose, at my request.

They very satisfactorily illustrate the point of impact and course of the ball, and the pathological conditions which followed, and upon which the diagnosis and treatment were based.

I desire to say, in a brief review of the leading facts as to the general conduct of the case, that it has been apparent to the medical reader that my prognosis was favorable, and notwithstanding the mutations I augured a successful termination. It is but justice to myself to state that my prognosis was based on a lesion of minor importance. Had our diagnosis been correct, modern surgery should have conducted the case to a successful termination. I believe the medical profession, whom I address, will bear me out that the prognosis was correct if the diagnosis had been also correct. I was not always able, during the progress of the case, to account for many of the more profound symptoms, and yet could not succeed in learning of any more extensive or complicated lesions than were first suspected. I desire to make the inquiry whether more extensive explorations could have been safely made, or whether the condition presented—a knowledge of the relative position of the patient to the assassin, the character of the missile, and the condition of the lesion and symptoms which follow—would have directed the investigation toward the actual track and lodgement of the ball, the track of the ball presenting a course of entrance downward and forward to the point of impingement upon

the eleventh rib, and being then deflected to the left at almost a right angle, passing behind the kidney, perforating the intervertebral cartilage and first lumbar vertebræ anterior and to the left of the kidney, and finding its lodgement below the left extremity of the pancreas, wounding in its track the splenic artery. I would ask if any known instrument or means of exploration has ever been presented to the profession capable of tracing before the death of said patient the course of this bullet? Also whether the conditions could have been improved or mitigated, or his life preserved longer by any other line of treatment; whether, in view of the facts, modern conservative surgery could offer anything more for the comfort or recovery of the illustrious patient.

It is proper to state, in conclusion, that most approved antiseptic dressings were used during the entire progress of the case.

The following is the report of the autopsy, to which reference has been made:

*Record of the Post-mortem Examination of the Body of President J. A. Garfield, made September* 20, 1881, *commencing at* 4.30 P.M., *eighteen hours after death, at Francklyn Cottage, Elberon, New Jersey.*

Present and assisting: Dr. D. W. Bliss, Surgeon-General J. K. Barnes, U. S. Army, Surgeon J. J. Woodward, U. S. Army, Dr. Robert Reyburn, Dr. Frank H. Hamilton, Dr. D. Hayes Agnew, Dr. Andrew H. Smith, of Elberon (and New York), and Acting Assistant Surgeon D. S. Lamb, of the Army Medical Museum, Washington, D. C.

Before commencing the examination, a consultation was held by these physicians, in a room adjoining that in which the body lay, and it was unanimously agreed that the dissection should be made by Dr. Lamb, and that Surgeon Woodward should record the observations made. It was further unanimously agreed that the cranium should not be opened. Surgeon Woodward then proposed that the examination should be conducted as follows:

That the body should be viewed externally, and any morbid appearances existing recorded; that a catheter should then be passed into the wound, as was done during life, to wash it out, for the purpose of assisting to find the position of the bullet; that a long incision should next be made from the superior extremity of the sternum to the pubes, and this crossed by a transverse one just below the umbilicus; that the abdominal flaps thus made should then be turned back and the abdominal viscera examined; that after the abdominal cavity was opened the position of the bullet should be ascertained, if possible, before making any further incision; and that, finally, the thoracic viscera should be examined.

This order of procedure was unanimously agreed to.

The examination was then proceeded with, and the following *external appearances* were observed:

The body was considerably emaciated, but the face was much less wasted than the limbs. A preservative fluid had been injected by the embalmer, a few hours before, into the left femoral artery. The pipes used for the purpose were still in position. The anterior surface of the body presented no abnormal appearances, and there was no ecchymosis or other discoloration of any part of the front of the abdomen.

Just below the right ear, and a little behind it, there was an oval ulcerated opening, about half an inch in long diameter, from which some sanious pus was escaping, but no tumefaction could be observed in the parotid region.

A considerable number of purpura-like spots were scattered thickly over the left scapula, and thence forward as far as the axilla. They ranged from one-eighth to one fourth of an inch in diameter, were slightly elevated and furfuraceous on the surface, and many of them were confluent in groups of two to four, or more. A similar, but much less abundant eruption was observed sparsely scattered over the corresponding region on the right side.

An oval excavated ulcer about an inch long, the result of a small carbuncle, was seated over the spinous process of the tenth dorsal vertebra. Over the sacrum there were four small bed-sores, the largest about half an inch in diameter. A few acne pustules, and a number of irregular spots of post-mortem hypostatic congestion were scattered over the shoulders, back, and buttocks. The inferior part of the scrotum was much discolored by hypostatic congestion. A group of hemorrhoidal tumors, rather larger than a walnut, protruded from the anus.

The depressed cicatrix of the wound made by the pistol-bullet was recognized over the tenth intercostal space, three and one-half inches to the right of the vertebral spines. A deep linear incision (made in part by the operation of July 24th, and extended by that of August 8th) occupied a position closely corresponding to the upper border of the right twelfth rib. It commenced posteriorly about two inches from the vertebral spines, and extended forward a little more than three inches. At the anterior extremity of this incision there was a deep, nearly square abraded surface about an inch across.

A well-oiled flexible catheter, fourteen inches long, was then passed into this wound, as had been done to wash it out during life. More resistance was at first encountered than had usually been the case, but after several trials the catheter entered, without any violence, to its full length. It was then left in position, and the body disposed supinely for the examination of the viscera.

The *cranium* was not opened.

A long incision was made from the superior extremity of the sternum to the pubis, followed by a transverse incision crossing the abdomen just below the umbilicus. The four flaps thus formed were turned back and the abdominal viscera exposed. The subcutaneous adipose tissue divided by the incision was little more than one-eighth of an inch thick over the thorax, but was thicker over the abdomen, being about one-fourth of an inch thick along the linea alba, and as much as one-half inch thick toward the outer extremity of the transverse incision.

On *inspection of the abdominal viscera in situ*, the transverse colon was observed to lie a little above the line of the umbilicus. It was firmly adherent to the anterior edge of the liver. The greater omentum covered the intestines pretty thoroughly from the transverse colon almost to the pubes. It was still quite fat, and was very much blackened by venous congestion. On both sides its lateral margins were adherent to the abdominal parietes opposite the eleventh and twelfth ribs. On the left side the adhesions were numerous, firm, well organized, and probably old.* On the right side there were a few

* These adhesions, and the firm ones on the right side, as well as those of the spleen, possibly date back to an attack of chronic dysentery, from which the patient is said to have suffered during the civil war.

similar adhesions, and a number of more delicate and probably recent ones.

A mass of black, coagulated blood covered and concealed the spleen and the left margin of the greater omentum. On raising the omentum it was found that this blood-mass extended through the left lumbar and iliac regions and dipped down into the pelvis, in which there was some clotted blood and rather more than a pint of bloody fluid.* The blood-coagula having been turned out and collected, measured very nearly a pint. It was now evident that secondary hemorrhage had been the immediate cause of death, but the point from which the blood had escaped was not at once apparent.

The omentum was not adherent to the intestines, which were moderately distended with gas. No intestinal adhesions were found other than those between the transverse colon and the liver, already mentioned.

The abdominal cavity being now washed out as thoroughly as possible, a fruitless attempt was made to obtain some indication of the position of the bullet before making any further incision. By pushing the intestines aside, the extremity of the catheter, which had been passed into the wound, could be felt between the peritoneum and the right iliac fascia; but it had evidently doubled upon itself, and, although a prolonged search was made, nothing could be seen or felt to indicate the presence of the bullet, either in that region or elsewhere.

The abdominal viscera were then carefully removed from the body, placed in suitable vessels, and examined *seriatim*, with the following results:

The adhesions between the liver and the transverse colon proved to bound an *abscess-cavity* between the under-surface of the liver, the transverse colon, and the transverse mesocolon, which involved the gall-bladder, and extended to about the same distance on each side of it, measuring six inches transversely and four inches from before backward. This cavity was lined by a thick pyogenic membrane, which completely replaced the capsule of that part of the under-surface of the liver occupied by the abscess. It contained about two ounces of greenish yellow fluid—a mixture of pus and biliary matter. This abscess did not involve any portion of the substance of the liver except the surface with which it was in contact, and no communication could be detected between it and any part of the wound.

Some recent peritoneal adhesions existed between the upper surface of the right lobe of the liver and the diaphragm. The *liver* was larger than normal, weighing eighty-four ounces; its substance was firm, but of a pale yellowish color on its surface and throughout the interior of the organ, from fatty degeneration. No evidence that it had been penetrated by the bullet could be found, nor were there any abscesses or infarctions in any part of its tissue.

The *spleen* was connected to the diaphragm by firm, probably old, peritoneal adhesions. There were several rather deep congenital fissures in its margins, giving it a lobulated appearance. It was abnormally large, weighing eighteen ounces; of a very dark lake-red color both on the surface and on section. Its parenchyma was soft and flabby, but contained no abscesses or infarctions.

There were some recent peritoneal adhesions between the posterior wall of the *stomach* and the posterior abdominal parietes. With this exception no abnormities were discovered in the stomach or *intestines*, nor were any other evidences of general or local peritonitis found besides those already specified.

The *right kidney* weighed six ounces, the *left kidney* seven. Just beneath the capsule of the left kidney, at about the middle of its convex border, there was a little abscess one-third of an inch in diameter, and there were three small serous cysts on the convex border of the right kidney, just beneath the capsule; in other respects the tissue of both kidneys was normal in appearance and texture.

The *urinary bladder* was empty.

Behind the right kidney, after the removal of that organ from the body, the dilated *track of the bullet* was dissected into. It was found that from the point at which it had fractured the right eleventh rib (three and one-half inches to the right of the vertebral spines) the missile had gone to the left, obliquely forward, passing through the body of the first lumbar vertebra and lodging in the adipose connective tissue immediately below the lower border of the pancreas, about two and one-half inches to the left of the spinal column, and behind the peritoneum. It had become completely encysted.

The track of the bullet between the point at which it had fractured the eleventh rib and that at which it entered the first lumbar vertebra was considerably dilated, and the pus had burrowed downward through the adipose tissue behind the right kidney, and thence had found its way between the peritoneum and the right iliac fascia, making a descending channel which extended almost to the groin. The adipose tissue behind the kidney in the vicinity of this descending channel was much thickened and condensed by inflammation. In the channel, which was found almost free from pus, lay the flexible catheter introduced into the wound at the commencement of the autopsy; its extremity was found doubled upon itself, immediately beneath the peritoneum, reposing upon the iliac fascia, where the channel was dilated into a pouch of considerable size. This long descending channel, now clearly seen to have been caused by the burrowing of pus from the wound, was supposed during life to have been the track of the bullet.

The last dorsal, together with the first and second lumbar vertebra and the twelfth rib, were then removed from the body for more thorough examination.

When this examination was made, it was found that the bullet had penetrated the first lumbar vertebra in the upper part of the right side of its body. The aperture by which it entered involved the intervertebral cartilage next above, and was situated just below and anterior to the intervertebral foramen, from which its upper margin was about one-fourth of an inch distant. Passing obliquely to the left, and forward through the upper part of the body of the first lumbar vertebra, the bullet emerged by an aperture, the centre of which was about one-half inch to the left of the median line, and which also involved the intervertebral cartilage next above. The cancellated tissue of the body of the first lumbar vertebra was very much comminuted and the fragments somewhat displaced. Several deep fissures extended from the track of the bullet into the lower part of the body of the twelfth dorsal vertebra. Others extended through the first lumbar vertebra into the intervertebral cartilage between it and the second lumbar vertebra. Both this cartilage and that next above were partly destroyed by ulceration. A number of

* A large part of this fluid had probably transuded from the injecting material of the embalmer.

PRESIDENT GARFIELD'S CASE.—Pathological Specimens and Anatomical Cuts, showing course of ball.

minute fragments from the fractured lumbar vertebra had been driven into the adjacent soft parts.

It was further found that the right twelfth rib also was fractured at a point one and one-fourth inch to the right of the transverse process of the twelfth dorsal vertebra; this injury had not been recognized during life.

On sawing through the vertebra, a little to the right of the median line, it was found that the spinal canal was not involved by the track of the ball. The spinal cord, and other contents of this portion of the spinal canal, presented no abnormal appearances. The rest of the spinal cord was not examined.

Beyond the first lumbar vertebra, the bullet continued to go to the left, passing behind the pancreas to the point where it was found. Here it was enveloped in a firm cyst of connective tissue, which contained, besides the ball, a minute quantity of inspissated, somewhat cheesy pus, which formed a thin layer over a portion of the surface of the lead. There was also a black shred adherent to a part of the cyst-wall, which proved, on microscopical examination, to be the remains of a blood-clot. For about an inch from this cyst the track of the ball behind the pancreas was completely obliterated by the healing process. Thence, as far backward as the body of the first lumbar vertebra, the track was filled with coagulated blood, which extended on the left into an irregular space rent in the adjoining adipose tissue behind the peritoneum and above the pancreas. The blood had worked its way to the left, bursting finally through the peritoneum behind the spleen into the abdominal cavity. The rending of the tissues by the extravasation of this blood was undoubtedly the cause of the paroxysms of pain which occurred a short time before death.

This mass of coagulated blood was of irregular form, and nearly as large as a man's fist. It could be distinctly seen from in front through the peritoneum, after its sight behind the greater curvature of the stomach had been exposed by the dissection of the greater omentum from the stomach, and especially after some delicate adhesions between the stomach and the part of the peritoneum covering the blood-mass had been broken down by the fingers. From the relations of the mass as thus seen, it was believed that the hemorrhage had proceeded from one of the mesenteric arteries, but as it was clear that a minute dissection would be required to determine the particular branch involved, it was agreed that the infiltrated tissues and the adjoining soft parts should be preserved for subsequent study.

On the examination and dissection made in accordance with this agreement, it was found that the fatal hemorrhage proceeded from a rent, nearly four-tenths of an inch long, in the main trunk of the splenic artery, two and one-half inches to the left of the cœliac axis. This rent must have occurred at least several days before death, since the everted edges in the slit in the vessel were united by firm adhesions to the surrounding connective tissue, thus forming an almost continuous wall bounding the adjoining portion of the blood-clot. Moreover, the peripheral portion of the clot in this vicinity was disposed in pretty firm concentric layers. It was further found that the cyst below the lower margin of the pancreas, in which the bullet was found, was situated three and one-half inches to the left of the cœliac axis.

Besides the mass of coagulated blood just described, another, about the size of a walnut, was found in the greater omentum, near the splenic extremity of the stomach. The communication, if any, between this and the larger hemorrhagic mass could not be made out.

The examination of the *thoracic viscera* resulted as follows

The *heart* weighed eleven ounces. All the cavities were entirely empty except the right ventricle, in which a few shreds of soft, reddish, coagulated blood adhered to the internal surface. On the surface of the mitral valve there were several spots of fatty degeneration; with this exception the cardiac valves were normal. The muscular tissue of the heart was soft, and tore easily. A few spots of fatty degeneration existed in the lining membrane of the aorta just above the semilunar valves, and a slender clot of fibrin was found in the aorta, where it was divided, about two inches from these valves, for the removal of the heart.

On the right side slight pleuritic adhesions existed between the convex surface of the lower lobe of the lung and the costal pleura, and firm adhesions between the anterior edge of the lower lobe, the pericardium, and the diaphragm. The *right lung* weighed thirty-two ounces. The posterior part of the fissure, between its upper and lower lobes, was congenitally incomplete. The lower lobe of the right lung was hypostatically congested, and considerable portions, especially toward its base, were the seat of broncho pneumonia. The bronchial tubes contained a considerable quantity of stringy muco-pus; their mucous surface was reddened by catarrhal bronchitis. The lung-tissue was œdematous,* but contained no abscesses or infarctions.

On the left side the lower lobe of the lung was bound behind to the costal pleura, above to the upper lobe, and below to the diaphragm, by pretty firm pleuritic adhesions. The *left lung* weighed twenty-seven ounces. The condition of the bronchial tubes and of the lung-tissue was very nearly the same as on the right side, the chief difference being that the area of the broncho-pneumonia in the lower lobe was much less extensive in the left lung than in the right. In the lateral part of the lower lobe of the left lung, and about an inch from its pleural surface, there was a group of four minute areas of gray hepatization, each about one-eighth of an inch in diameter. There were no infarctions and no abscesses in any part of the lung-tissue.

The surgeons assisting at the autopsy were unanimously of the opinion that, on reviewing the history of the case in connection with the autopsy, it is quite evident that the different suppurating surfaces, and especially the fractured spongy tissue of the vertebra, furnish a sufficient explanation of the septic conditions which existed during life.

About an hour after the post-mortem examination was completed, the physicians named at the commencement of this report assembled for further consultation in an adjoining cottage; a brief outline of the results of the post-mortem examination was drawn up, signed by all the physicians, and handed to private secretary J. Stanley Brown, who was requested to furnish copies to the newspaper press.

As the above report contains paragraphs detailing

* A part, at least, of this condition was doubtless due to the extravasation of the injecting fluid used by the embalmer.

the observations made at Washington on the pathological specimens preserved for that purpose, the names of Drs. F. H. Hamilton, D. Hayes Agnew, and A. H. Smith, are not appended to it. It has, however, been submitted to them, and they have given their assent to the other portions of the report.

## SURGICO-ANATOMICAL STUDY OF THE GUNSHOT WOUND OF PRESIDENT GARFIELD.

By FANEUIL D. WEISSE, M.D.,

PROFESSOR OF PRACTICAL AND SURGICAL ANATOMY, MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK.

After the autopsy on the remains of the late President, performed September 20, 1881, the following seemed to have been the course of the fatal ball after it entered the President's body, and the same was verified by actual dissections:

*The ball entered opposite the tenth intercostal space, about four inches to the right of the median line of the back. It ranged in a direction forward and downward, inclining a little from right to left. It perforated to the plane of the ribs through the skin, subcutaneous tissue, fascia, the latissimus dorsi, serratus posticus inferior, and sacro-lumbalis muscles. It impinged upon the eleventh rib (the most movable of all the ribs), which it crowded to a plane anterior to that of the twelfth. It produced a comminuted fracture of the eleventh rib. The impact of the ball on the eleventh rib caused it to turn on its axis, and from there it was deflected to the left. It perforated the eleventh external intercostal muscle and the sub-pleural portion of the diaphragm just above the right ligamentum arcuatum externum. It tracked through the connective and adipose tissue between the superior portion of the right kidney and the twelfth rib to the spinal column. It pierced the attachment of the right psoas magnus muscle to the first lumbar vertebra. It entered the body of the first lumbar vertebra from right to left. It emerged from the left of the spine, pierced the left psoas magnus muscle attachment, and entered a plane of connective and adipose tissue between the left kidney posteriorly and the left half of the pancreas anteriorly. It crossed the posterior surface of the pancreas obliquely to the left and from above downward to its point of lodgement. It wounded the splenic artery in its transit across the pancreas (the splenic artery presenting in the track of the ball, it seemed more than probable that it, and not the mesenteric, would prove, upon a careful dissection, to have been the injured vessel), from which source the final hemorrhage occurred which burst into the peritoneal cavity.*

I visited Washington with Dr. Geo. F. Shrady, upon the invitation of Dr. D. W. Bliss. At that time Dr. Shrady was informed of the above theory and dissections, but Dr. Bliss knew nothing of these anatomical investigations. Dr. Bliss related to Dr. Shrady and myself a detailed history of the President's case from July 2d to the time of his death. The pathological specimens taken from the body were placed at our disposal by Surgeon J. J. Woodward, U.S.A., in charge of the Army Medical Museum (where the specimens are), and we studied them carefully. Drs. Woodward and Lamb had made careful dissections of the pathological specimens, by which were revealed the following conditions, which lack of time had rendered impossible to have been known at the time of the issue of the Elberon autopsy bulletin:

*First*—The existence of a united fracture of the right twelfth rib.

*Second.*—The entrance of the ball at the right side of the intervertebral fibro-cartilage, between the twelfth dorsal and the first lumbar vertebræ, involving the adjoining portion of the body of the first lumbar vertebra, anterior to the right intervertebral foramen, between the pedicles of the twelfth dorsal and the first lumbar vertebræ.

*Third.*—The transit of the ball through the superior half of the body of the first lumbar vertebra, from right to left and obliquely forward and downward, producing a comminuted fracture of the body of the vertebra.

*Fourth.*—That the intervertebral fibro-cartilage between the first and second lumbar vertebræ had been injured, by the comminution of the body of the vertebra contiguous to it.

*Fifth.*—That the left anterior inferior edge of the body of the twelfth dorsal vertebra was broken away.

*Sixth.*—The evidences of a traumatic aneurism in communication with the splenic artery, at about two and one-half inches from its origin from the cœliac axis.

*Seventh.*—The cyst which contained the ball was found at the inferior border of the external left third of the pancreas posterior to the peritoneum, viz., the posterior inferior layer of the lesser omentum, which becomes the anterior superior layer of the transverse meso-colon.

*Eighth.*—The imperviousness of the track of the ball for an inch or more from the cyst.

The specimen of the abdominal viscera did not present anything bearing upon the location of the collection of pus to the right of the vertebral column described in the Elberon autopsy bulletin.

Reviewing the theory previously deduced, with these additional facts, there was found only this to add:

*In that portion of its course after deflection from the eleventh rib to the spine, the ball grazed the anterior surface of the twelfth rib, producing a simple fracture of it.*

*The transit of the ball through the spine had been defined, but remained virtually the same.*

The injuries inflicted by the ball may be epitomized as follows:

*First.*—A compound comminuted fracture of the eleventh rib.

*Second.*—A compound fracture of the twelfth rib.

*Third.*—A compound comminuted fracture of the body of the first lumbar vertebra, complicated with injury to the intervertebral fibro-cartilages above and below that vertebra, and the breaking off of the border of the twelfth dorsal vertebra.

*Fourth.*—A wound of the splenic artery.

The anatomical reasons for the sequelæ of the above injuries are:

*Sequelæ of the first injury.*—The compound comminuted fracture of the eleventh rib developed the superficial abscess opened by the first operation; the debris of the comminuted rib—thrown by the deflection of the ball downward into the substance of the muscles of the parietes—was the direct cause of irritation, etc.

*Sequelæ of the third injury.*—The concussion to the spinal column had its expression in the symmetrical pains at the peripheral distributions of the right and left sacral plexuses, below the knees, indicating disturbance of their contributive spinal nerves, which constitute the major portion of the cauda equina within the lumbar region of the column.

The pain in the right inguinal region and of the right side of the scrotum would find its explanation in a special impression upon the right first lumbar nerve—the anterior branches of which are the right ilio-hypogastric and ilio-inguinal nerves distributing thereto—which is in close relation with the first lumbar vertebra.

The comminuted fracture of the lumbar vertebra, the injury to the twelfth dorsal, and the injured intervertebral fibro-cartilages determined a consecutive destructive inflammation, the pus from which drained to the right. The pus, however, did not altogether follow the track of the ball posterior to the right kidney; some of it passed anterior to the right kidney, dissecting its way posterior to the peritoneum.

The pus, taking the posterior course, dissected its way down in the post-visceral and extra-peritoneal (sub-serous) areolar tissue, interior to the transversalis fascia of the abdominal parietes, the process ultimately resulting in the sinus, which extended to the iliac fossa.

The pus taking the anterior course did not have an outlet and a reservoir of it accumulated between the right kidney posteriorly and the peritoneum covering the liver and the colon anteriorly.

The contiguity of this pus to the liver and colon induced a protecting localized adhesion of the opposed peritoneal surfaces, investing the liver on the one hand, and the hepatic flexure and right half of the transverse colon on the other. These conditions were verified at the autopsy: "An abscess-cavity, six inches by four in dimensions, was found in the vicinity of the gall-bladder, between the liver and the transverse colon, which were strongly adherent. It did not involve the substance of the liver, and no communication was found between it and the wound." It is possible that there was an error as to the location of this pus; in exposing the abscess *in situ* the adhesions between the liver and colon were progressively separated, and the collection of pus—really behind the posterior plane of the peritoneum, in the right lumbar region—as it bulged forward, gave the semblance of lodgement between the liver and colon.

*Sequelæ of the fourth injury.*—The injury to the splenic artery developed a traumatic aneurism, as appeared in the dissected specimen. The location was such that it obstructed the track of the ball to the left side of the spine, in which position it determined two reparative processes: 1st, the obliteration of the track of the ball to the left of the first lumbar vertebra, which prevented the drainage of pus in that direction; 2d, the lodged ball, sealed hermetically from access of air by the closure of its track, became at once encysted.

The surgical anatomy of this memorable case of gunshot wound admits of the following conclusions:

*First.*—It is a matter of great regret that the autopsy was not made from the back instead of the anterior plane of the body. The bullet entered from behind, and from this direction it should have been followed; after which the internal organs could have been examined for evidences of any remote effects of the wound. Dissections demonstrate, conclusively, the advantages, in this particular case, of such a course, as it would have exposed the lesions and the encysted ball *in situ*.

*Second.*—The impossibility at any time to have safely or even successfully probed the wound so as to find the ball.

*Third.*—The ball as lodged was shut in beneath the abdominal parietes and kidney posteriorly, and the abdominal parietes and spleen laterally and to the left. In this location no operation was warranted for its removal, there having been no evidence of its presence there.

*Fourth.*—Had the point of lodgement of the ball been known, the fact of its not producing any local irritation—the formation of an abscess around it—would have been a positive contra-indication against any operation looking to its removal.

*Fifth.*—If an abscess had formed around the ball instead of its becoming encysted, the pus might have burst into the peritoneal cavity or pointed in the left loin below the kidney, and formed a similar post-visceral and extra-peritoneal sinus to the one that existed upon the right side.

The rupture into the peritoneal cavity would probably have been provided against by the occurrence of suitably protecting peritoneal adhesions. Had the sinus formed, it would have afforded a clue to a correct diagnosis; and under these conditions, after an incision had been made to allow the escape of pus at the left side, an exploratory operation, with the sinus as a guide to the ball, might have been warranted, even to the determining its positive location, and possibly its extraction. Indeed, the ball itself might have dropped into the left sinus.

*Sixth.—It was anatomically possible for a ball deflected downward from the eleventh rib to take the same course as did the sinus to the iliac fossa, and there was afforded—by the rapidity with which this sinus formed; the readiness with which the drainage tubes passed; the fact that the incision of the second operation tapped the sinus below the twelfth rib; the fact that the wound of entrance of the ball healed so promptly after the incisions below; the existence early in the case of a point of tenderness in the right iliac fossa and the subsequent recognizable induration there, which gradually diminished—sufficient grounds to warrant the diagnosis that was arrived at and maintained up to the time of the death of the patient, especially so in the absence of any evidence that the ball had taken a different course.*

---

LARGE CALCULUS EXTRACTED FROM THE BLADDER OF A WOMAN BY MEANS OF RAPID DILATATION OF THE URETHRA.—The patient was a woman aged eighty-two, complaining of dysuria and frequency of micturition, and very much debilitated by a long period of suffering. She was forced to pass water every fifteen minutes, and the act was preceded and followed by intense pain. The urine was scanty, and loaded with muco-pus. Exploration revealed stone in the bladder. The woman was anæsthetized to the surgical degree, and the urethra rapidly dilated to 3 ctm. with Buch and Hugier's dilator. The finger was then introduced into the bladder, and the position of the calculus, which lay across the internal opening of the urethra, was rectified. The stone was then removed by means of a small pair of forceps, a limited incision in the upper and lower commissures of the urethra being made to allow its extraction. The dimensions of the calculus were as follows: lesser diameter, 28 mm.; greater diameter, 42 mm.; lesser circumference, 82 mm.; greater circumference, 105 mm. Its weight was 22 grammes; its composition, carbonate of calcium.

OVARIOTOMY IN SOUTH AMERICA.—The first successful operation of this kind, in South America, was performed five or six months ago, by Dr. Ponte, of the Medical Faculty of Caracas.

## SURGICAL AND PATHOLOGICAL REFLECTIONS ON PRESIDENT GARFIELD'S WOUND.

By GEORGE F. SHRADY, M.D.,

SURGEON TO THE PRESBYTERIAN AND ST. FRANCIS' HOSPITALS, NEW YORK.

The case of the late President Garfield has, from its purely surgical aspect, interested every member of the profession throughout the civilized world. Never before has a wound been studied with more care, from the meagre and unsatisfactory data heretofore obtainable, and never before has the accumulated experience of surgeons been more directly applied and more anxiously concentrated upon the welfare of any one patient. The reasons for this are too obvious to mention here.

Having had unusual opportunities for studying the case with Prof. Faneuil D. Weisse, of this city, we having been invited by Dr. D. W. Bliss to examine the morbid specimens in the Army Medical Museum, at Washington, it seems incumbent upon me that I should, from certain pathological and surgical standpoints, make a direct and unbiassed statement.

It cannot be expected that, under the circumstances, a detailed history of the President's case will be given. Such necessarily has been done by the surgeon in charge, who, by actual presence at the bedside, is the only one who can speak with authority concerning the symptoms presented. Nor would I presume at this time to add to the already extensive literature of the subject, were it not considered necessary to do so by the gentleman who so kindly gave me every facility for examination, and who has deemed it a duty which I owe to the profession.

It is proper that I should speak only concerning those points of which there is a direct knowledge on my part, and offer such impressions as are founded thereon.

It is well established by the autopsy that the ball entered four inches to the right of the median line in the tenth intercostal space, and passed forward and downward, impinging upon the eleventh rib about three and one-half inches from the median line of the spinal column. The missile was then deflected to the left and downward, grazing the twelfth rib, which it fractured, and, continuing its course, entered the right side of the intervertebral fibro-cartilage between the twelfth dorsal and first lumbar vertebræ.

The ball then passed through the upper half of the body of the first lumbar vertebra, emerged on the antero-lateral face of the body of the same vertebra, half an inch to the left of the median line, thus throwing the track of the missile forward. Thence it passed behind the pancreas and lodged at the inferior border of the left external third of that organ. In its course behind the pancreas the ball wounded the trunk of the splenic artery. No vital organ was injured. The wound of the splenic artery gave rise to a traumatic aneurism which undoubtedly commenced to form immediately, and it was the final rupturing of this sac into the peritoneal cavity which, as is now well known, caused the death of the patient, and satisfactorily explained all the symptoms during the last hours of his life.

The ball was thoroughly encysted, and the portion of the track adjoining it, for a distance of an inch, was completely closed. The position of the blood-sac evidently accounted for both of these conditions. This aneurism, situated to the left of the spinal column, and between the latter and the ball, apparently pressed upon that portion of the track next the missile and closed it. At the same time, as can easily be understood, the sac-aneurism was thus placed in the direct track of the ball. This is certainly a very significant fact in connection with the probably fatal results in case any extensive exploration of the bullet-wound had been attempted. The aneurism was lined by concentric layers of fibrine which showed nature's efforts to obliterate the sac in the usual manner.

The evidences that the sac had not formed recently were made clear by a study of its pathological conditions. The opening in the splenic artery was on the superior and posterior aspect of its tortuous trunk directly in the track of the ball. The edges of this opening were sharply defined but were gradually bevelled to be incorporated with the walls of the attached blood-sac. This condition would indicate that the coats of the artery were cut completely through during the transit of the ball, and were not merely grazed and afterward opened by ulceration. It would thus appear that the aneurism was formed immediately after the injury and at that time attained its full size. Besides, the sac itself was evidently of long formation, as was shown not only by the firm condensation of its tissue, and its intimate attachment to the edges of the cut in the artery but by the number and apparent age of the concentric layers lining it. The burst portion of this sac was on its left anterior aspect, where not only its walls, but the different concentric layers were thinnest. The immediate invitation for this rupture was the degenerated condition of that portion of the sac, as indicated by progressive and destructive changes in its tissues. It is quite probable, as suggested by Dr. Bliss, that the blood escaping from this sac did not at first find its way into the peritoneal cavity, but that there were distinct hemorrhages into the adjoining tissues, at stated intervals, until the blood ploughed its way forward and to the left, finally escaping into the peritoneal cavity. On this supposition, the occurrence of the intermittent pains in the side, likened by the patient to those of angina pectoris, is, as expressed by Dr. Bliss, very satisfactorily explained.

The question naturally suggests itself at this point, whether or no, if the traumatic aneurism had not existed at the point indicated, it would have been possible to have made a safe and satisfactory exploration of the bullet track through the spinal column. The distance from the point of entrance of the missile in the integument to the commencement of the track through the body of the lumbar vertebra was fully five inches. This fact would, for very obvious reasons, have prevented the exploration of the right side of the vertebra by the finger, the only safe way, under the circumstances, to have made the exploration. The relations of the track to the right side of the vertebra would have made it impossible to have guided intelligently any probe in the required direction. Had the latter been possible, no surgeon would have taken the risks of passing it through the vertebra presumably in such close proximity with the spinal cord. But allowing, for the sake of argument, that a probe could have been introduced safely through the body of the injured vertebra, and that there was no difficulty in tracing the track beyond it, other difficulties and dangers would have presented themselves. In the first place, there is no instrument known to surgeons that could have demonstrated

the actual existence of the ball at its point of lodgement. Loosely attached as it was to the lower border of the pancreas, it would have been pushed before the point of the instrument without affording sufficient resistance to indicate its presence to the operator. Further, by such an attempt, especially during the earlier periods of the case before encystment took place, there would have been a liability of dislodging the ball and causing it to fall into the cavity of the lesser omentum, and by its presence there inviting peritonitis and its attendant evils.

There was no cloth or other foreign material found in the track of the ball, and Surgeon J. J. Woodward, whose testimony concerning microscopical appearances cannot be questioned, informed me that the two small collections of matter found within the cyst, one of a whitish and the other of a blackish appearance, were respectively inspissated pus and a collection of blood-pigments. All the appearance seemed to point to the fact that the reparative processes around the ball commenced to take place immediately after the lodgement of the missile. The left kidney, which contained the abscess, was not preserved, but the report of the autopsy, to the effect that the suppuration was under the capsule of this organ, has an important bearing upon the precise cause of the lesion.

The body of the first lumbar vertebra presented the appearances of carious degeneration in the course of the wound, and, as far as could be judged by an examination of the dried specimen, the intervertebral cartilages above and below it were involved in the same necrotic process. The spinal canal was not involved in the injury. It was stated to me that the shattered eleventh rib had firmly united. This bone was unfortunately not preserved. The twelfth ribs were, however, intact, and had been removed along with the last dorsal, first, and second lumbar vertebræ. The broken portions of the right twelfth rib were firmly united by bone. As the liver had not been saved, the relations of the abscess to it and the surrounding parts were not demonstrable. It was stated, however, that the abscess was situated, as has already been described in the official autopsy, and that it was a closed sac of pus behind the peritoneum. Professor Weisse very ingeniously explained its presence there as a direct drainage in front of the right kidney from the lesion of the spine. This collection of pus at no time had, as far as could be learned, any direct connection with the external wound, although Dr. Bliss entertained such impression from the fact that at times a different character of pus was forced by pressure upon the abdominal walls from the orifice of the supposed track of the bullet.

In following the detailed history of this remarkable case, no significant symptoms were discoverable that would point to the injury of the spinal column as found at the autopsy, save the symmetrical involvement of the nerve-origins by the concussion of the ball. When the first bulletins announced that the President had been shot near the spine, and that there were attendant nerve-disturbances in the lower extremities, a natural and legitimate inference was an injury of some kind to the spinal cord. But when the nerve-symptoms in the lower extremities disappeared there was, for good reasons, a different diagnosis made.

As to the question of septic infection, about which so much has been said, it is well enough in this connection to recognize the fact that there are three principal grades or types of fever that follow the receipt of wounds. A mild form, known to all hospital surgeons, as *traumatic fever*. It occurs early in the history of the case, runs an acute course usually in a few days, and rarely occupies a week. Its phenomena are notably those connected with any high fever, and fatal results are not common. Then we have simple *septicæmia*, so-called, which is usually associated with the idea that some decomposing organic substance has found its way into the blood. In such cases the wound, if visible, exhibits an altered character. It is apt to be humid, swollen, and may be gangrenous. The fever is persistent, with corresponding rise in temperature. The pulse is constantly frequent, and more or less sweating is present. There are occasional attacks of mild shiverings, there may be vomiting, and often there is profuse diarrhœa. At post-mortem examination there is nothing found which may be regarded as characteristic. The spleen is apt to be enlarged and softened, and so too the liver and kidneys. The blood also coagulates imperfectly. Exceptionally, in long-continued cases, there are said to be emboli in distant parts, with resultant abscesses. It is known to us in connection with dissection-wounds.

The third grade or type is what is known among hospital surgeons as *pyæmia*. In reality, the term is an incorrect one, and should not be used. Much better would it be to designate the condition as one of metastatic septicæmia. It is characterized by intermittent rigors, in which the temperature rises from three to five degrees, and then ascends still higher during the fever, but falls during the sweating, all of which phenomena follow one another much as in a case of ague.

These exacerbations have no periodicity as in ague. They occur at any time of day or night, at first often with long intervals, and then with short intermissions. The duration of the disease depends much on the nature of the accident, the strength of the patient, and the activity of the treatment. He may survive but a few days, or many months, in which latter case the disease may be classified as chronic.

Circumscribed abscesses are found in the internal organs; or, if the disease has been very acute, these abscesses may be diffuse. When such an affection is established, the pus becomes scanty, thin, and altered in color, or it may be arrested altogether for a time; wounds or abscesses show little tendency to heal; the skin is apt to be bathed in a peculiarly sticky sweat, and the breath has a characteristic sweet odor. Marked prostration follows each exacerbation, and the patient sinks to a lower level of vitality, in which attacks of delirium are not uncommon.

It remains to decide to which class the President's case belonged. It was evidently not a case of traumatic fever, nor could it be classed with the milder form, called simple septicæmia.

From a careful study of the symptoms in connection with the examination of the autopsical lesions, the conclusion seems inevitable that the case was one which, commencing as the milder form of septicæmia, gradually developed into the graver metastatic variety, or that generally understood as chronic pyæmia. It is apparent that the lines of distinction between the latter conditions cannot be clearly drawn in President Garfield's case; but it must be admitted that the weight of evidence is on the side of metastatic septicæmia, clinically and pathologically. In fact, it is safe to assert that the symptoms pointed so directly toward the existence of this condition, that it was a matter of great surprise that

more metastatic abscesses were not discovered at the autopsy. The assumption in favor of metastatic septicæmia would be satisfactorily proved by the abscess of the kidney and the multiple abscesses in the parotid, which were within the capsules of the respective organs. The theory of Dr. Bliss regarding the production of the abscesses in the parotid is ingenious and rational, as is also his explanation that the abscess in the kidney was of traumatic origin; but it is not necessary to have an independent theory for each of these conditions. It is certainly much easier to account for them by one general explanation, as by such means all the points in the clinical and pathological history can be made consistent and reconcilable. There can be no doubt that the chief source of septic infection was the wound through the lumbar vertebra.

Examining all the conditions of the wound and its relations to contiguous parts, it is easy to explain, as the result of Prof. Weisse's careful and exhaustive studies at the cadaver, that the "possible course of the ball" (*vide* MEDICAL RECORD, July 16, 1881) was the result of a burrowing sinus from the lesions of the ribs and spine, and that the track of the pus was in the direction of the least resistance. It was the only course which a ball deflected downward could have taken without injury to vital organs, and this was the diagnosis subsequently made by the surgeons. Nature, in reality, made a track for the pus, which on very reasonable grounds was supposed to have been the original course of the ball.

Knowing the facts, as demonstrated by the pathological lesions revealed in the President's case, each surgeon is qualified to judge as to the practicability of making extensive explorations of the wound and as to the propriety of removing the ball by operation. It is well to consider at the start that the bullet, as such, had no immediate influence upon the progress of the case, and that the real causes of trouble were connected with the conditions of the track, viz., the broken ribs, the lesions of the spinal column, and the existence of the aneurismal sac. But if the exact location of the missile had been known, and under the supposition that its presence was a source of irritation, the necessary exploration had been made, the probe would have perforated the traumatic aneurism, and the almost instant death of the patient would have been the result. From the position of the wound and the attendant conditions, through drainage at the inguinal region was impossible, and its employment as a means of treatment would, in all probability, have added an extra complication.

From my personal examinations of the pathological specimens, and as the result of an extended and careful study of the history of the case, with every opportunity for examination of details, I am convinced that the treatment of the President was judicious and skilful from the time he was first visited by the physicians in charge until his weary struggle for life was at an end.

---

THE STENCHES FROM HUNTER'S POINT are not so pronounced as formerly. The State Board of Health, with commendable zeal, has succeeded in abating the nuisances connected with several of the manufactories of manure in that locality. There are, however, one or two of these establishments which persist in their objectionable methods, and will probably, in due time, be held to legal accountability.

# Progress of Medical Science.

AMYL NITRITE AS A CARDIAC STIMULANT.—Dr. Edward T. Reichert, in a recent paper on the potassium nitrite, claimed that the nitrites, in small or moderate doses, acted as direct cardiac stimulants, and endeavored, while discussing their physiological action, to clearly show wherein the deductions of certain observers on the action of the amyl compound had been erroneously drawn, and why the results of certain experiments undoubtedly corroborated his belief. He has resumed a discussion of the subject in the *New York Medical Journal*, July, 1881, and from it we learn that the nitrites act in two ways to affect the blood-pressure: the one by directly stimulating the heart, and the second by depressing the vaso-motor system, especially its centres. The stimulating effects on the heart ultimately give way to depression, and the reason why the amyl nitrite does not cause a rise of pressure, like the potassium salt, resides in the fact that its vaso-motor action is comparatively more intense, and is more than sufficient to overcome the stimulant effect on the heart. This fact was proven by a comparison with the results of Brunton's experiments. Accepting the deductions as made from the results of Brunton's and Dugan's experiments, it is obvious that the action of the amyl nitrite is identical with that of the alkaline salts, and, consequently, it is a direct cardiac stimulant, increasing the frequency of the heart's action and the amount of work done in a given time. Clinically speaking, it is indicated in chloroform narcosis because its use is followed by a marked acceleration of the heart's action and flushing of the face. Two cases of fatty heart serve to illustrate the stimulant action, and the beneficial results, as a consequence, from its use. The first is that of Osgood, who found it to act with remarkable efficacy, so much so that he believes death would have ensued in a few moments if it had not been given. The second case is one of Janeway's, in which, after the complete extinction of the radial pulse, the nitrite caused it to become full. There are also two cases of valvular disease. Wood states that in his case the effect of the drug in relieving the pang when other remedies failed was astonishing; and Jones tells of a case of a woman who suffered from cardiac dyspnœa, with a dilated hypertrophy of both ventricles (the dilatation being in excess), a feeble circulation, extreme anasarca, pulmonary œdema, lividity of the face, and shortness of breath. The use of amyl nitrite produced most beneficial effects, and induced a pleasant glow all over the body, and on each occasion of its use she felt easier and more comfortable about the chest.

HYDROCELE IN THE FEMALE.—Dr. William C. Wile has reported two cases of this kind, in the *American Journal of Obstetrics*, July, 1881. It is a very rare malady, and, if of ancient origin, was not recognized by the practitioners of those days. The cause is obscure. Labor would seem to have some influence in producing it. The diagnosis will not be difficult in the extra-peritoneal variety. Its diaphanous character, absence of pain, slow growth, not receding into the abdominal cavity, either by taxis or while in the recumbent position—peculiar fluidy feel imparted to the fingers during manipulation, the absence of resonance on percussion, no constitutional excitement, all go to make the diagnosis compara-

tively easy; and the only affection it could possibly be confounded with is hernia. To make assurance doubly sure, however, a small exploring-needle, or what is still better, the fine needle of a hypodermic syringe, should be passed in, when its character will at once become apparent. If it prove to be a hernia, no harm will be done by the puncture. After the diagnosis is made, evacuate by the respirator, and then the injection of tincture of iodine into the sac is preferable to incision and drainage.

In the first case which came under Dr. Wile's observation, a diagnosis had been repeatedly made as one of hernia, and a truss actually applied and allowed to be worn for nearly a year and a half. The patient was a married woman, thirty-seven years old, the mother of four children, the youngest one and one-half year old. Eight years ago she was delivered with instruments, after a long and painful labor. She had a slow getting up, and a short time after she had commenced to go about the house she noticed an enlargement of the left labium. It gave her no pain or inconvenience. She sought medical advice, and was told that she had a hernia. After the delivery of her last child, it enlarged very rapidly. When the patient came under Dr. Wile's observation, she exhibited a soft, fluctuating tumor in the left labium, the size of a large hen's-egg. Hydrocele was suspected, and the diagnosis confirmed when the needle had been introduced. About one-half drachm of tincture of iodine was injected, which caused an active inflammation, which gradually subsided in the course of the next six days. The second case was a primapara, aged forty-four years. A tumor appeared in the right labium, which slowly increased until it grew to the size of a small hen's egg; no pain or inconvenience from it whatever; never receded in the abdominal cavity while in the recumbent position, and could not be reduced in any position. Instead of healing nicely, the sac took on suppurative action, which necessitated laying open the wound, and after dissecting as much of the sac as was possible, the wound was packed with oakum and allowed to heal by granulation. Dr. Wile was assisted by Dr. Horatio R. Bigelow, of Washington, D. C., in his search of the literature on the subject, and, after a very exhaustive search through the library of the Surgeon-General's office, failed to find more than one case on record among the journals of this country and Europe.

Enchondroma of the Larynx.—An instance of this rare affection is reported by Ehrendorfer, in the *Archiv f. klin. Chirurgie*, vol. xxvi., p. 578. The patient was a woman, fifty-three years of age, who had become hoarse three years before, and had remained so, despite electrical treatment. At that time the left vocal cord was found to be paralyzed. A year later laryngoscopic examination disclosed, on the posterior wall of the larynx, close to the left vocal cord, a small tumor covered by healthy mucous membrane. The growth gradually enlarged, became ulcerated, and was regarded as carcinomatous. Three years after the development of the initial symptoms, deglutition and respiration became so much impeded that it was found necessary to perform tracheotomy. While introducing the canula, a piece of the tumor was accidentally torn off, and on examination proved to be cartilage. Three weeks later Billroth proceeded to extirpate the growth. Beginning at the hyoid bone, an incision was made on the left side of the neck, along the anterior border of the sterno-cleido-mastoid, for a distance of nine centimetres. The operator now separated, with blunt instruments, the tissues intervening between the incision and the left side of the larynx and pharynx, and, after thus exposing the posterior wall of the larynx, was able to enucleate the tumor with the fingers. The neoplasm was found to originate from the posterior surface of the posterior half of the cricoid cartilage, growing thence upward and backward, and finally penetrating into the interior of the larynx, between the arytenoid cartilages. At this point there was a hole in the mucous membrane large enough to admit the finger. After introducing a drainage-tube, the wound was closed with sutures, but had to be reopened five days later, the patient having had a chill. The cavity was found lined with a fibrinous deposit, which disappeared after several days, the wound then healing by granulation, although complete closure was retarded for a time by the escape through the wound of a part of the ingesta, probably through subsequent perforation of the œsophagus. The development of luxuriant granulations in the larynx necessitated the introduction of peculiarly constructed conical sounds for some time after the cicatrization of the external wound. The extirpated tumor was four centimetres long, three centimetres wide, and two centimetres thick, consisted of hyaline cartilage with an admixture of connective tissue, and contained several small and large cysts.—*Wiener med. Wochenschrift*, July 2, 1881.

Peculiar Plexiform Sarcoma of the Posterior Wall of the Pharynx.—The patient, a woman, forty-eight years of age, complained since two years of gradually increasing obstruction to deglutition. Examination with the laryngoscope disclosed a whitish, nodulated swelling, partly overlying the entrance to the larynx. The tumor could also be felt from the outside, and an enlarged lymphatic gland was noticed in the superior triangle of the neck. After vainly endeavoring to seize the growth from the mouth, Billroth performed pharyngotomy, dividing the pharynx and upper part of the œsophagus, after which the tumor presented itself to view. It was attached to the posterior wall of the pharynx by a pedicle of the thickness of a quill. The pedicle and its point of insertion were then excised, the pharyngeal and œsophageal wound sewed up, and the external wound closed, after previously extirpating the enlarged gland. Primary union. The tumor, the dimensions of which were four, two, and one and one-half centimetres respectively, possessed a structure similar to that of the early stage of cylindroma. The cells of which the cylinders were composed had none of the characteristics of epithelial cells. Groups of similar cells, but no cylinders, were found in the lymphatic gland. Cross-sections of the capillary vessels show their actively proliferating endothelia, aggregated here and there so as to resemble cancer-pearls.—*Wiener med. Wochenschrift*, July 2, 1881.

The Simultaneous Occurrence of Albumen and Sugar in the Urine.—According to Dr. Th. Frerichs, there are three conditions in which sugar and albumen occur together in the urine. These are: 1st, glycosuria; 2d, diabetes mellitus; and 3d, chyluria. In glycosuria, under which heading Frerichs classifies cases in which, for a varying length of time, small amounts of sugar are excreted without exerting any appreciably bad effect upon the nutrition of the individual, albuminuria is a very frequent complication, occurring in nearly fifty per cent. of the cases. The diseases in the course of

which glycosuria presents itself are acute and chronic cerebral affections. Thus, Frerichs found sugar and albumen in the urine in three cases of aneurism of the brain, which had ruptured into the ventricles, in four cases of extensive apoplectic effusion, two of purulent general meningitis, and one of chronic tubercular basilar meningitis. Extravasation of blood into the ventricles was common to all these cases except one, where the effusion involved a part of the cerebellum and the crus cerebri. Of the chronic form, which may last years, three cases were observed, all complicated by facial paralysis; there was from one and one-half to two per cent. of sugar in the urine, with a varying amount of albumen, one or the other constituent occasionally disappearing entirely for a time. No post-mortem examinations were obtainable. In all of the above cases the cause of the pathological secretion is, according to Frerichs, a lesion of the fourth ventricle, at and just above the diabetic point. The prognosis in the acute cases depends altogether upon the nature of the cerebral affection, being most favorable in meningitis, Frerichs himself having observed two recoveries. In chronic cases the prognosis must always be dubious, the subjects being usually individuals who are run down by mental over-work, and who are notoriously liable to apoplectic seizures.

Frerichs met with but few cases of diabetes mellitus complicated with nephritis—at most five per cent. of the cases—and most of these were affected with other conditions sufficient to give rise to albuminuria *per se*, thus: arteriosclerosis, phthisis pulmonum, cystitis, and arthritis with renal calculi. All cases of diabetes mellitus complicated with phthisis terminated fatally; others, where the albuminuria was dependent on cystitis and subsequent nephritis, ended in recovery. In chyluria, albumen, sugar and fat are found in the urine; but whether this is due, as has been assumed, to a reversed current in the lymphatics, is an open question. This much has been demonstrated by Brieger: when fat is excluded from the diet of the patient, none appears in the urine.—*Med.-chirurg. Rundschau*, June, 1881.

Treatment of Suppurating Buboes by Aspiration.—M. Le Pileur advises aspiration in the treatment of suppurative adenitis, no matter what the nature or origin of the disease may be. The operation should be deferred until the pus has collected and fluctuation is no longer doubtful. A cure is effected with almost invisible, or at least, very insignificant cicatrices. The duration of the trouble in the cases operated upon was short. Nineteen instances selected at random gave an average of about twenty-four days after the operation. The method mentioned has an inconvenience—one, however, which neither the physician nor the patient need hold as of much account: it necessitates surveillance with daily inspection.—*Annales de Dermatologie et de Syphilographie*, April, 1881.

Etiology, Pathogenesis, and Treatment of Chlorosis.—Zander concedes that chlorosis is substantially dependent upon a deficient formation of red blood-corpuscles, both as to number and quality, and that this condition may be relieved by increased absorption of iron. But he denies that iron is the only agent that is capable of curing chlorosis. Mother's and cow's milk contain more iron than is necessary for the nutrition of a child—at least the fæces contain appreciable amounts of the metal. The ordinary diet of man is also sufficiently rich in iron to satisfy the wants of the body. If, then, individuals become chlorotic by reason of an insufficiency of iron, the latter should be absent, or at least be found in very small quantity, in the excreta. Zander found that this was not the case. On examining the fæces in many cases of chlorosis where iron had not been administered, considerable amounts of the latter were always present. The fault lies, therefore, in a defective digestion and assimilation of iron—due, in all probability, to an insufficient gastric secretion of muriatic acid. Acting on this assumption, Zander prescribed this acid for all of his chlorotic patients, and obtained results more satisfactory and lasting than he had had with iron. Relapses, of course, were also met with, especially at the onset of menstruation; but they were readily overcome by repose and the renewal of medication.—*Med.-chirurg. Rundschau*, June, 1881.

Gastric Epilepsy and the Relations Existing between it and Certain Neuroses of the Vagus Nerve.—In a communication to the *Revue de Médecine* of June, 1881, Dr. Pommay states that the results of his researches have justified him in placing gastric epilepsy of males upon a level with uterine epilepsy of females. He cites several instances in which epileptiform attacks were due to disturbances of digestion. Many cases of epilepsy seen in full-blooded gourmands, the author thinks, are due rather to an overloaded condition of the stomach, than to a plethoric state of the blood-vessels. According to Kussmaul and Tenner, whom he cites, congestion of the cerebral arteries produces symptoms unlike those of epilepsy. In the case of plethoric individuals, there can be no doubt of active congestions unless there intervene a pathological factor of a different nature. Related to gastric epilepsy are those affections which have lately been grouped together under the name of neurosis of the pneumogastric. They are characterized by attacks of cardiac palpitation, oppression, disturbance of cardiac rhythm, and a feeling of hunger sometimes amounting to pain. These symptoms follow errors in diet, and disappear upon treatment directed to the digestive trouble. The feeling of hunger, sometimes increasing to pain, has been indicated by Hughlings-Jackson as the aura of gastric epilepsy. Dr. Pommay draws his conclusions as follows: 1st, digestive troubles may produce various nervous symptoms, due on the one hand to paralysis, on the other hand to an excitation of the pneumogastric nerve; 2d, these phenomena are of reflex nature, and are confined to the pneumogastric. They are produced by irritation of the sensory gastric filaments, and reflex excitation or paralysis of the cardiac branches; 3d, the phenomena of excitation occasion epileptic attacks, and those of paralysis give rise to cardiac disturbances; 4th, the age and condition of the patient seem to influence the mode of response to irritation; 5th, gastric epilepsy differs from other epilepsies, first, in its cause—errors of diet; secondly, in its symptoms, *i.e.*, vomiting of food, superadded to the ordinary symptoms of the attack; and thirdly, in its sequelæ, *i.e.*, gastric trouble.

Nature and Pathogenesis of Visceral Lesions Dependent upon Progressive Obliterating Endocarditis.—In the *résumé* of this very thorough paper, published in the May number of the *Revue de Médecine*, Dr. Martin makes the following statements: 1. The inner tunic of the majority of the arteries of the system, during almost the entire period of life, is subjected to irritations which inflame and thicken

it, and consequently induce a diminution of the quantity of blood in circulation. 2. Progressive obliterating endocarditis may be seen even in the first years of life, and in young children is principally localized in certain nutrient vessels supplying the first portion of the aorta, in which situation small atheromatous plaques are consequently developed. Later the process invades a larger number of arterioles, locating itself by preference in organs whose circulation and function are very active. 3. The progressive diminution of the amount of blood conveyed to a certain viscus, brings on an atrophy of its functional elements, and a corresponding development of connective tissue. This sclerosis begins as far away as possible from the affected arterial trunks, and in situations where the supply is most insufficient; it is not preceded by any lesions of the capillaries in that region. The functional cells in the neighborhood of its point of development appear healthy and uninflamed during the initial period, until the sclerotic tissue has undergone perceptible increase. There is nothing to prove that this sclerosis is the consequence of an inflammatory irritation; for this reason it has been called dystrophic sclerosis. 4. Progressive endarteritis accounts for, and shows the pathogenetic connection of a great many scleroses. It explains why cirrhosis may appear in one organ rather than in another, why the endarteritis may locate itself, primarily or after other such localizations, in the nutrient arterioles of the posterior region of the spinal cord, thus determining the lesion and the symptoms of ataxy. 5. Progressive endarteritis may occur as an acute lesion, especially in certain infectious maladies causing circulatory troubles which of themselves may suffice to cause death should such an important organ as the heart, for instance, become affected. 6. Irritant particles existing in the blood (as in gout, alcoholism, plumbism), cannot fail to hasten the evolution of and exaggerate chronic progressive endarteritis. As for the acute endarteritis of infectious diseases, the modern parasitic theories agree very well with its conception, and explain its evolution naturally. 7. The proliferative lesion beginning in the inner coat may remain localized there, but, as a rule, it spreads beyond it.

Valvular Ruptures of the Heart.—There are a certain number of instances of rupture of the heart, says Dr. Barié (*Revue de Médecine*, June, 1881), involving only the valvular apparatus, without any lesions of the cardiac walls or the thorax. These cases are much more rare than those of common rupture of the heart, implicating the walls of the ventricles and auricles, and the septa between these cavities. Rupture sometimes affects the semilunar valves of the aorta, and sometimes the auriculo-ventricular. No cases of rupture of the pulmonary semilunar valves are recorded. These accidents, in some patients, are of spontaneous origin, following a violent effort. In others the cause is a sudden and intense shock sustained by the thorax. When the rupture involves the aortic semilunar valves, it affects by preference that valve which corresponds to the interventricular septum, and especially the point of valvular implantation upon the aortic orifice. In rupture of the mitral, in no case was the valvular velum itself involved; in one case out of three of tricuspid rupture the velum was torn. Most cases of spontaneous ruptures followed a violent effort. Traumatic ruptures of the mitral appear to have occurred, as a rule, at the beginning of the ventricular systole: some, however, during cardiac repose. Aortic valvular rupture commonly took place during diastole. The prognosis of valvular rupture is grave. Out of thirty-five cases alluded to, twenty-four died. In semilunar rupture the accident is, perhaps, gravest when it involves a valve surmounted by the mouth of a coronary artery. In mitral rupture the prognosis is most serious when the lesion involves a fleshy column rather than the chordæ tendinæ. It is possible to produce valvular ruptures experimentally by augmenting the pressure to which the valves are subjected. It is difficult to so rupture the mitral, because the cardiac walls give way under lower pressure than the valves. In the process of estimating the pressure necessary to produce rupture, the manometer gave very varying results, ranging from one hundred and sixteen millimetres of mercury to four hundred and eighty-four millimetres. The resistance evidently varies for every heart, according to the more or less perfect integrity of its muscular walls.

The Late Manifestations of Syphilis in Old Persons.—The February number of the *Revue de Chirurgie* contains a contribution upon this subject by MM. Ferrier and Luc. According to them, in old persons syphilis occurs under two very different forms. It may show itself as the late manifestation of a disease contracted at a more or less remote period, or as early accidents resulting from recent syphilitic infection. The researches of the authors are based upon observations upon the persons of old females admitted to the surgical service of the Salpêtrière. Patients affected with visceral syphilis did not fall under their notice, as these were taken charge of by the medical division of the staff. The writers consider successively gummata of the skin and cellular tissue, those of the muscles and bones, and finally, cutaneous manifestations. In some cases the coincidence or succession of morbid manifestations served to determine the diagnosis of syphilis, the effects of treatment affording but little information in this respect. Many of the specific accidents described were but slightly, or not at all, influenced by the mixed or the iodide treatment carried on systematically for quite a length of time. The intervals of time between the primary lesions and these late accidents is worthy of consideration. In one instance the primary lesion had occurred at the age of twenty-six; the specific cutaneous affection for which the patient entered the hospital appeared at the age of sixty. Another patient had had a chancre when she was twenty-six years old; the syphilide appeared at the age of sixty-one. Had the absence of previous treatment had any influence upon the appearance of these late manifestations? This was regarded as possible, although the fact could not be definitely proved. At all events, the greater part of the cases observed had had no anterior specific treatment.

The authors endeavored to ascertain whether there was any reason why the late manifestations should preferably involve the cutaneous structure, the bones, and the cellular tissue. Their inquiries, however, failed to elicit satisfactory explanations.

In concluding, they call the attention of clinicians to the following facts: 1. The relative frequency of late syphilitic manifestations in old persons. 2. The features presented by such lesions, according as they affect the integument, the cellular tissue, the muscles, or the bones. 3. Finally, the slight efficiency possessed by rational therapy—mercurial, mixed, or iodide of potassium treatment—in ameliorating or curing these late accidents.

# THE MEDICAL RECORD:

## A Weekly Journal of Medicine and Surgery.

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, October 8, 1881.

## THE LATE PRESIDENT GARFIELD'S CASE.

THE surgical aspects of the case of the late President Garfield assume a new importance in view of the results of the autopsical revelations. The time has arrived for the settlement of all questions regarding diagnosis, prognosis, and treatment, by an appeal to the dead body, and by the careful and conscientious study of the lesions revealed by the post-mortem.

No case has ever occurred in surgical history that has invited more study by the profession or commanded a greater interest with the people. In its discussion by the secular press the entire world has not only been impressed with its importance as a political event, but with its remarkable history as a surgical case. In fact, it is safe to say that its purely surgical aspects have been made paramount to every other consideration in connection with it. Even the daily bulletins, scanned as they were by millions, have of themselves, in consequence of the public anxiety for the distinguished patient, been the means of popularizing many technical terms in medicine and many methods of surgical procedure which have heretofore been the exclusive property of the profession. Now every intelligent citizen is enabled, as the result of a pardonable interest in the details of diagnosis and treatment, to appreciate, in a great measure. the relative value of the many important questions involved, even in the discussion of the purely technical side of the case. Not only the profession, but the people, have awaited with no little interest the discussion of the subject from the purely medical and surgical aspects; and now that the end has come and the time for writing the history has arrived, the general professional study of the case has commenced.

The medical and surgical history of President Garfield's case is now appropriately presented to the profession and to the public for the first time, by the gentleman most competent to speak, and who as surgeon in charge has been immediately responsible from shortly after the time of the infliction of the wound at the Pennsylvania depot, to the final passing away of President Garfield at Elberon. To such as may read the explicit, straightforward narration of Dr. Bliss as now presented, it must appear that there are many new and important points connected with diagnosis and treatment which have never before appeared in print, and that very many matters of detail heretofore in doubt are now given to his professional brethren in a direct and authoritative way. He is now in a position to be judged by his peers as to the course which he pursued, and to speak *ex cathedra* upon all matters of practical interest connected with the performance of the duties of his office as the principal and trusted professional adviser of the President.

It is not necessary here to do more than comment in a general way upon the history of the case as given by Dr. Bliss, and upon the autopsy, which he appends. Whatever else may be said concerning the case, it must be conceded that all its salient points are well brought out, and all the statements made with a conscientious desire for the truth and in the higher interests of scientific surgery. From the facts as presented, it appears that the case was well treated from the beginning, and that nothing was left undone, either in the way of meeting existing conditions or anticipating possible contingencies. In this history are answered many important questions, particularly relating to the examination of the wound, the treatment of the various complications, as well as the proper division of responsibility among those whom he chose for his counsellors. He is now given an opportunity of presenting the reasons for his general course in the conduct of the case, and to explain, in a direct and manly way, the cause of errors. For such as were unavoidable he will be generously excused, while for such as are matters for individual judgment he must receive his meed of credit, and put at rest the many criticisms of those who never saw his patient, and could never know his patient's wants. The suggestions as to what might have been done are now answered by the simple statement of one who was constantly at the bedside, and who, with rare acuteness and wise forethought, was ready and eager to meet indications as they actually occurred.

The mistake in diagnosis, deplorable as it may seem, was natural, if not positively unavoidable, considering all the conditions present. In fact, now that the autopsy has disclosed the precise locality of the ball, it is a matter for congratulation that its real track was not suspected before death. As proved by the autopsy, there lay directly in the course of the missile the blood-sac, an injury to which, by an explorative operation, must have resulted in instant death. Never before has it been

so clearly demonstrated that the sin of omission in surgery (if such a term may be allowable in this connection) was more excusable than that of commission in the shape of officious operative interference. It is comforting to think that the error of diagnosis had no possible bearing upon the ultimate result, and that, in fact, it was a means of avoiding serious mishaps in other directions. It appears quite evident, in view of the autopsical examination, that not only would it have been dangerous, but impossible, to track the ball through its course; while all attempts at removal by operation, allowing that its precise locality could be made out, were out of the question. Certain it is that the autopsy proved that the missile could not have been reached from any direction and removed without sacrificing the life of the patient by the wounding of large and important vessels in the neighborhood, inflicting irreparable injury to vital organs, and thus directly inviting death.

As has been proven by the autopsy, the ball could not have been in a better situation for more rapid and complete encystment. The traumatic aneurism formed upon the wounded splenic artery was in such a situation as virtually to press upon the portion of the track next to the ball, and secure its prompt closure. The ball itself might have remained harmless in that position for an indefinite number of years. But in saying this much it must be considered that there were other attendant conditions which made it impossible for the patient to recover. These, taken together, were mortal from the beginning, and the prolongation of the life of the patient against such heavy odds could only be accomplished by the exercise of the most watchful care, consummate skill, and sound conservatism not only of Dr. Bliss, but of all the gentlemen who so nobly and generously shared with him the dreadful responsibilities of the case during all the anxious moments and the darkest hours. As an evidence that the dressings were properly made and the freest possible drainage given to all accessible parts of the wound, it is only necessary to refer to the fact that the original track in the external soft parts and that the fractured twelfth rib had firmly united by bone, which could hardly have been possible if for any considerable period it had been bathed in pus. For the same reason the eleventh rib, which unfortunately was not removed at the autopsy, is said to have been in a state of healthy repair.

### A SUGGESTION FOR THE AMERICAN ACADEMY OF MEDICINE.

We made a brief reference to the work of this organization at the time of its meeting in this city.

At that time, as heretofore, we took occasion to express a cordial wish for the success of the association in the excellent objects toward which it aims.

One can give good wishes to the academy without entirely approving of its methods, and there certainly appears to be something lacking in these methods, else why does the academy get along so slowly. It is now in its sixth year. It is a national association.

The persons eligible to membership must number among the thousands. Yet its membership is only, we understand, about two hundred. The number of persons with a degree of Bachelor or Master of Arts who yearly graduate in medicine certainly reaches among the hundreds, but the yearly additions to the academy are, we are informed, only between ten and twenty. This certainly looks like a lack of energy, and very naturally excites the query:

Why is not something done to increase the membership, when the available candidates are so numerous?

For one thing, the academy does not make its objects, or even its existence sufficiently known. And, furthermore, the fee for membership is at present unnecessarily great.

The society stands somewhat in the position of the *Index Medicus*, which every one admits is an admirable periodical, and urges his neighbor to take it. But the esteem is not great enough to disturb the local relations of the pocket-book. There is this difference, however: the Academy does not need the five dollars. And there are, we doubt not, hundreds of young men who would willingly become members, and who would take an earnest interest in the society, but who are hardly able, if inclined, to give their five dollars for an initiation fee, and ten dollars more for a diploma, when the return is practically nothing, or rather, is nothing practical. Let there be some arrangement for rebating the fees, which the society does not need, and let the society make itself more widely known. Then, we venture to say, its annual membership would be increased by hundreds instead of tens. With increased membership would come greater activity and power to influence the education of medical men in the way toward which the society aspires.

### THE CRUSADE AGAINST POOR MILK.

Unusually energetic efforts have been made recently to prevent the introduction of poor milk into the city. Once or twice every week the milk inspectors have made systematic examinations of the milk brought from New Jersey, Long Island, or the counties above the metropolis. Not long ago a number of children in a large city orphan asylum were taken sick. The cause was suspected to be the inferior quality of the milk. The samples were obtained, and found apparently to have been watered or skimmed. The dealer was arrested, but escaped justice, it is said, through political influence.

Last week about five thousand quarts of skimmed and adulterated milk were seized and poured into

the street. The spilling of bad milk is to be kept up by the authorities, we are told, as long as it continues to be sent into the city.

The old-fashioned plan of simply watering milk has been largely superseded of late by the dairymen. The present method is to mix skimmed and unskimmed milk together. Other dealers simply remove one-fourth or more of the cream, and sell the rest for unskimmed milk. Occasionally a little soda or salt is put in milk to keep up the specific gravity. The proportion of water in milk averages about eighty-eight parts per hundred. In watered milk this amount is increased usually by about four per cent.

The amount of milk consumed in New York City is not accurately known, but it is certainly enormous. There are at least six thousand places here where milk is sold, while some large dealers sell five or six thousand quarts a day. The necessity of watching over this milk-supply is very apparent, but is, after all, not felt as it should be.

The Board of Health is to be praised for the work it is doing, and yet it cannot legally do one-half of what is needed. Our milk-inspectors can only keep out milk that is poor in nutritive qualities. The talk about finding "adulterated" and "poisoned" milk is, in most cases at least, sheer nonsense. Milk is not adulterated except with water or salts, neither of which constitute adulterations in the serious sense of the word. Poisoned milk is not intentionally sold, unless the milk from diseased animals be called such. And then it is not often practicable or possible for the inspectors to detect it.

It was forcibly shown by Dr. Brush, in an article in THE RECORD a few weeks ago, that one of the greatest dangers from our milk-supply lay in the fact that some of the milk comes from diseased cows. The herds of the dairymen are liable to be affected by some form of disease, such as pleuropneumonia or tuberculosis, garget, or foot and mouth disease, all the time. There are many dairymen, according to Dr. Brush, who use the milk from cows which have calved only a day or two before. In bovine tuberculosis it is not impossible that the milk contains a specific poison, weak indeed in power, but able to affect the system of infants. In most of the ordinary diseases of cattle it is probable that the milk is affected chiefly as regards the albumen and caseine. The former increases in amount, being present in the colostrum corpuscles, while the caseine at the same time diminishes. Dr. Brush considers the true evidence of the good quality of milk to lie in the fact that there is a normal proportion between the sugar and albumen on the one hand, and the caseine on the other.

Altogether it is very evident that though our milk inspectors are very active in destroying skimmed and watered milk, they do not strike at the root of the evils of our milk supply. There should be some laws to protect us against milk from diseased cattle, and, we might add, against milk from dairies where there is typhoid fever, diphtheria, or scarlet fever.

These are things that the profession would do well to agitate when the proper time comes; meanwhile, something can be done by private effort. There are already organizations in the city which claim to furnish pure milk from healthy cows. These companies have their herds inspected monthly by veterinarians. Their existence clearly shows that some of our population appreciate the necessity of having pure milk. There should be efforts to make this feeling more widespread.

---

### MALARIA IN NEW ENGLAND.

NOT long ago we called attention to the fact that malaria had been showing itself in various parts of New England, where it has heretofore for many years been comparatively unknown. The *Boston Medical and Surgical Journal* has been discussing the subject in its columns, and furnishes some interesting facts connected therewith.

Malaria is not a new disease to New England, but has appeared now and then in different localities ever since the settlement of the country. In Dr. Green's centennial address, delivered before the Massachusetts Medical Society, last summer, several references to the disease are quoted. The Reverend Mr. Danforth, of Roxbury, during the winter of 1660, makes the following entry in the church records: "The Lord was pleased to visite vs with epidemical colds, coughs, agues and fevers." Later, in 1671, he writes: "This summer many were visited with ye ague and fever," and again in the same year he records: "Agues and fevers prevailed much among vs about ye Bay, and fluxes and vomiting in Boston." Another writer, in 1691, speaks of the "burning and spotted Fevers, shaking Agues, dry Belly Achs, plague of the Guts, and divers other sore distempers" which afflicted the plantation.

There are other records of the existence of malaria in New England at later periods. Nevertheless, it is a fact that for a considerable time this form of disease has shown itself endemically in but very few sections in the States in question. It is, we believe, about five years since it began to travel up the Connecticut and along the sea-coast. It has now reached some of the river towns in lower Vermont, and has been quite prevalent at several points in Western Massachusetts, along the Connecticut River valley. Cases also occurred at Providence, R. I., and in the vicinity of Boston. According to a report made by the Connecticut State Board of Health, the malarial wave is gradually extending over that State. The only rule which seems to be observed is, that it follows up the river valleys, spreading on either side. It also travels along the coast-line, extending thence

inland. Local causes do not apparently develop the disease, although marshy ground, newly turned soil, etc., have in some cases increased the amount or modified its character.

The reasons for the appearance of this remarkable malarial wave are as yet quite obscure. The Connecticut Board of Health is, however, studying the question, and doubtless the sanitary boards of other States will soon take action. It is a matter that certainly deserves attention, and local physicians have now an opportunity to make some very useful observations.

---

### THE SCOURGE OF ITALY.

PELLAGRA is a disease which is rarely described in ordinary text-books, and only receives a brief notice in works on the skin. It has a terrible significance, however, to the inhabitants of Italy, where the disease has widely prevailed for many years. Its gradual increase, and the devastation it creates, have led to some very extensive investigations into its cause and nature. And these investigations have more than a local interest.

Pellagra is usually, but with no good reason, classed among skin-diseases. It has been called elephantiasis italica, but it bears a closer resemblance to the bronzed skin-disease of Addison than to any form of elephantiasis.

It is a chronic disease, and is characterized by three especially marked trains of symptoms. These are: an eruption on the skin, intestinal derangement, and various nervous phenomena. Behind all these, however, there is a profound disturbance of nutrition.

The disease generally begins in the spring with some prodromata, such as neuralgia, muscular twitchings, dyspepsia, and general malaise. An erythematous eruption then appears upon the exposed parts of the body, the hands being first affected. Sometimes the skin is darkly bronzed, while occasionally it is red and swollen as in erysipelas.

The digestive organs become disturbed, appetite is lost, and there is diarrhœa or constipation.

The general nutrition is affected. All the subcutaneous fat disappears—then the muscles waste. The pulse becomes rapid and thready; the temperature declines. The mind becomes weakened—mania, dementia, and epilepsy may ensue. But generally there is a dull languor, with weakened muscles and partial loss of cutaneous sensibility. Finally, says one writer, "the patient, dried up, hard to the touch, inert, apathetic, motionless, insentient, with sunken eyes and deadened look, becomes a mere mummy, unconsciously awaiting the opening of the grave."

The symptoms disappear in part during the winter, but reappear in a more aggravated form in the spring. Thus the disease continues with winter improvement and summer relapses for from two to ten or twelve years. In the more chronic form, imbecility or suicidal mania are almost sure to develop. The patient suffers also from anæmia, dropsy, and intestinal hemorrhage.

Such are, in brief, the chief clinical features of the disease.

A remarkably exhaustive account of these, as well as of the etiology of pellagra, has been furnished in a report ("Annali di Agricoltura") published by the Italian minister of agriculture. From this we learn that pellagra is endemic in only four places in the world: Italy, Spain, Southern France, and Roumania. It is found chiefly in Italy, however, and only in the northern half of that country. Here, however, its ravages are frightful and appalling. In four provinces, those of Brescia, Padua, Piacenza, and Ferrara, one in every fifteen or twenty of the rural population is affected with this fatal léprosy. In thirty one other provinces the disease fastens upon from one to three per cent. of the rural population. We say rural population, because pellagra does not develop in the cities, though it is sometimes brought there.

The cause of pellagra is found in a study of the condition and mode of life of the Italian peasant. The disease prevails in the most fruitful and beautiful parts of Italy. But this beauty and fruitfulness are at the expense of those who labor to produce it. The farmer of Italy is one of the most ill-paid, ill-housed, underfed, and overworked creatures in the world, if we may credit the report referred to. His wages are from ten to twenty or twenty-five cents a day, upon which he must support himself and family. He works ten or eleven hours a day; his home is filthy and unwholesome; the water he drinks is bad; his food (and this is the vital point) consists chiefly of maize. This maize is often imperfectly ripened, and becomes the seat of the growth of a fungus (*Sporiosorium maïdis*). It is ground into flour; but, as the peasant can rarely afford a fire, the flour is made into large cakes, and a number of these are baked, or half-baked, at a time. Before they can be all eaten, decomposition sets in, and the food becomes too loathsome for anything but the voracity of famine. The peasant, of course, is not entirely confined to the corn. In the summer especially, frogs are largely eaten. Still poisoned and insufficient food form his usual supply. Since Italy is not the only country where overwork and starvation prevail, however, a more special cause of the pellagra must be looked for. This, it is asserted, is found in the poisoned maize.

The overwork and famine will not induce pellagra; neither will the diseased corn; but the two acting together are sufficient. This view, though controverted by some, is the one that is still generally held.

At a meeting of the Academy of Medicine of Paris not long ago, an interesting discussion took place regarding the pathology of pellagra. It was questioned whether we should regard it as a morbid entity due to a single specific cause, or should class it as a cachexia brought on by multiple causes. The opinion receiving the strongest endorsement was that pellagra was a disease in which nutrition was peculiarly affected because the causes were peculiar, but that it could hardly be said to be due to a single specific cause. Other agencies than those found in Italy might and do occasionally induce the affection. But it is the altered maize acting on an impoverished organism which most easily and surely produces the nutritive disturbances of pellagra.

The remedy for the disease is a matter for the statesman more than the physician. And the history of pellagra shows how closely the work and investigations of the medical men bear upon the welfare of the country. For these investigations have proved that to remove the pellagra from Italy it is only necessary to fed her peasants.

Yet, after all, this is not so easy. The great landed proprietors say that they cannot pay higher wages, for their estates are so heavily taxed. The Government cannot lighten the taxes because it must support its immense standing army. We have then the spectacle of a great country gradually reducing its inhabitants to cretinism (for pellagra is increasing) in order to sustain an armed peace.

### OUR ILLUSTRATIONS.

We have to congratulate our readers upon the full illustrations of President Garfield's case we are able to present. Dr. D. W. Bliss invited Mr. Max Cohn to make the drawings from the actual specimens (Figs. 1, 2, 3), and the masterly manner in which he has accomplished the task, together with the other explanatory cuts, leaves nothing to be desired. We have also to commend the faithful reproduction of the original drawings by the Moss Engraving Co.

Ethiops Mineral in Pertussis.—In an epidemic of pertussis, prevailing in Castelluchio, Dr. Tedolei claims to have obtained exceedingly gratifying results from the exhibition of ethiops mineral. To children under one year, fourteen centigrammes were given in a day, in four doses, this amount being gradually increased by thirteen centigrammes. The remedy is to be continued until cure is complete; but, as soon as its favorable action begins to be apparent, the dose is to be diminished.

Death Produced by Living Fish.—The *Journal de Médecine d'Algérie* reports eleven cases in which the custom indulged in by fishermen of killing fish with their teeth has been productive of various accidents. In two cases mentioned, a small fish became lodged in the respiratory tract, causing the death of the man.

## Reviews and Notices of Books.

Transactions of the Eleventh Annual Session of the Medical Society of Virginia, held in Danville, October 19 to 21, 1880.

The contents of this volume are limited, but the contributions are all practical, and show experience and good sense. We commend especially Dr. Joseph A. White's "Remarks about Common Functional Eye Troubles," Dr. Semple's report on "Recent Advances in Medicine," the discussion on "Summer Complaints of Infants," and Dr. C. R. Cullen's paper on "New Remedies."

The Mother's Guide in the Management and Feeding of Infants. By John M. Keating, M.D. 12mo, pp. 118. Philadelphia: H. C. Lea's Sons & Co. 1881.

This is a sensible little work, giving much valuable and practical information to the nursing mother.

A Guide to the Use of the Laryngoscope in General Practice. By Gordon Holmes, L.R.C.P., Edinburgh. 12mo, pp. 60. Philadelphia: Presley Blakiston.

The author has labored very successfully to give practical instruction in the use of the laryngoscope.

Indigestion, Biliousness, and Gout in its Protean Aspects. Part I.—Indigestion and Biliousness. By J. Milner Fothergill, M.D., London. 12mo, pp. 316. New York: William Wood & Co. 1881.

Dr. Fothergill is always entertaining and instructive. In the present work he fully sustains this reputation, not only in regard to his division and manner of treating the subject, but the thoroughly practical bearing of his observations. With the breadth of view which comes of large experience and extensive and varied study, he is able to overlook a vast field, and cull therefrom what may be of practical use to the worker and learner. And all in the charming style of an entertaining story teller. Such a gift is so seldom possessed by medical writers, that when found it deserves at least a passing reference.

The digestive act, involving as it does so many points connected with chemistry and physiology, is considered in all its manifold relations, and a happy medium of utility is reached in selecting and commenting upon such points only as can be turned to practical account by the physician. The proper preparation of food is a subject which claims much attention, and the reasons for the different degrees of digestibility of food-substances are given with clearness of expression and comprehensiveness of scope which leaves nothing to be desired.

The reader is made to believe that, although the digestive act is a complicated one, comprehending the function of every part of the intestinal tract, it is possible not only to understand it in its totality, but to study the relations of its different divisions. The different forms of digestion are described, and the departures from the normal standard are given in necessary detail. Particularly is this the case with liver digestion, our author availing himself of the recent labors of physiologists to throw light upon the so-called bilious derangements, and to explain the true relations of the bile with albuminoids. His remarks upon this subject are particularly interesting, and will serve to reconcile the popular notions

regarding liver indigestion with the demonstrated facts of scientific observation. In the treatment of biliousness, Dr. Fothergill goes back to first principles by showing in a clear and systematic manner how, after correcting errors, we may be able to prevent their recurrence. With no great faith in physic, he does not hesitate to prescribe a mercurial purge when such is required, and his reasons for so doing should be read by every routinist. In regard to other prescriptions the same remark may be made. Each and every direction is based upon the general principle that the physician's office is to understand Nature and be thus enabled to aid her; to interpret her wants and to make due allowances for any deficiencies of development or function which may be discovered. The relations of digestion to habits of life, to methods of living, and to the perfect nutrition of the body, are treated in a masterly manner, and abound in practical hints of the greatest possible utility to the practising physician. Altogether the work is a remarkably comprehensive study of a subject which is too little understood by the majority of medical men.

## Obituary.

### DR. JAMES P. WHITE, M.D.,

BUFFALO, N. Y.

A VERY wide circle of medical men will learn with deep regret of the death of Dr. James P. White, of Buffalo, which occurred September 28th.

Dr. White was born in 1810. He was educated at Middlebury Academy. He received his medical education at Fairfield Medical College, and subsequently at Jefferson Medical College, from which place he graduated in 1834. He immediately began practising in Buffalo. He subsequently studied in Edinburgh under Professor Simpson, and with prominent professors of medicine in Paris and Vienna. Dr. White's professional contemporaries included Drs. Julius F. Miner, Austin Flint, Frank H. Hamilton, and others generally well known. Dr. White was one of the prime movers, with Drs. Hamilton and Flint, in founding the University of Buffalo, with its Chamber of Medicine, in 1846. He was also foremost in founding the Young Men's Association, the Fine Arts Academy, the Edward Street Foundling Asylum, the Provident Insane Asylum, St. John's Episcopal Church, and the State Asylum for the Insane. Of the latter he was president from its completion. He was one of ten citizens who paid for the survey of Buffalo's beautiful park, laid out by Frederick Law Olmstead. Dr. White was the first professor in this country to give clinical lectures on midwifery, and was only successful after much opposition. In the winter of 1870–71 he was invited to deliver a series of lectures before Bellevue Medical College, of this city, in place of Professor George T. Elliott, who was sick. Dr. White delivered the lectures, but with characteristic generosity paid his own expenses and handed the fees to Professor Elliott. The faculty of the college presented him with a beautifully embossed copy of complimentary resolutions, and the students made a similar presentation. Dr. White was a contributor to the *American Journal of Medical Science* and the Buffalo *Medical Journal*. At the time of his death he was a member of the Erie County Medical Society, the New York State Medical Society, the American Gynecological Society, and the American Medical Association, of which he was the first vice-president. He was one of the vice-presidents of the International Medical Congress held in Philadelphia during the centennial year. In spite of his success and many honors, Dr. White was pre-eminently a domestic man. His home and family were always first in his mind. He leaves a wife and a son—James P. White.

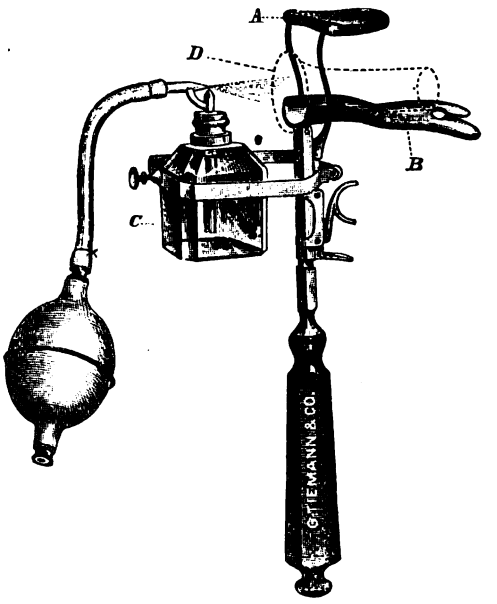
## New Instruments.

### SPECULAR TONGUE DEPRESSOR, MOUTH-GAG, AND SPRAY.

By C. J. CLEBORNE, M.D.,

MEDICAL INSPECTOR U. S. NAVY.

THIS form of tongue-depressor (B) will be found more powerful than others in controlling muscular action of the tongue in nervous persons and unmanageable children, while its reflecting surface specially adapts it to operations upon the throat and palate.



By it the tongue is not only depressed, but it may be forced forward if necessary, and the jaws may be separated to any extent by the gag and depressor.

The gag (A) is worked by a ratchet or thumb-screw, so as to be readily raised or lowered by the operator.

A Cohen's (C) or long-tubed atomizer may be used (with or without the glass tube, D) in the movable bottle-holder attached to the shaft of the instrument, so that the spray can be turned in any direction by the operator, who holds the handle of the tongue-depressor, and thus controls the mouth and throat of his patient.

The gag and atomizer may be detached by a simple movement, leaving the instrument an ordinary tongue-depressor.

The handle is made hollow to contain throat-brushes, caustics, or other articles needed in small operations upon the mouth, throat, or palate.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from September 25, 1881, to October 1, 1881.*

ALEXANDER, R. H., Major and Surgeon. Relieved from duty in Department of the East, to take effect October 1, 1881, and granted leave of absence for three months, with permission to apply for one month's extension; at expiration thereof to report by letter to the Surgeon-General. S. O. 215, A. G. O., September 19. 1881.

HUNTINGTON, D. L., Major and Surgeon. Relieved from duty as Attending Surgeon at the Soldiers' Home, D. C., and to report in person to the Surgeon-General for duty as Curator of the Army Medical Museum, and to take charge of the Division of Surgical Records of the Surgeon-General's office. S. O. 217, A. G. O., September 24, 1881.

BROWN, HARVEY E., Major and Surgeon, granted leave of absence for four months. S. O. 220, A. G. O., September 29, 1881.

KING, WILLIAM H., Capt. and Asst. Surgeon. When relieved by Asst. Surgeon Turrill, to proceed to Governor's Island, N. Y. H., and report in person at these Headquarters. S. O. 170, Department of the East, September 24, 1881.

EWEN, CLARENCE, Capt. and Asst. Surgeon. Granted leave of absence for one year on surgeon's certificate of disability, with permission to go beyond sea. S. 220, C. S., A. G. O.

DEWITT, C., Capt. and Asst. Surgeon, now on leave of absence, to report in person to the Governor of the Soldiers' Home, D. C., for duty as Attending Surgeon at the Home. S. O. 217, C. S., A. G. O.

HEIZMANN, CHAS., Capt. and Asst. Surgeon. Relieved from duty at Fort Townsend, W. T., and assigned to duty at Vancouver Barracks, W. T., as Post Medical Officer, relieving Asst. Surgeon Dickson. S. O. 135, Department of the Columbia, September 9, 1881.

HALL, JOHN D., Capt. and Asst. Surgeon. The leave of absence granted him in S. O. 141, August 4, 1881, Department of Dakota, is extended three months. S. O. 220, C. S., A. G. O.

SKINNER, J. O., Capt. and Asst. Surgeon. Relieved from duty at Fort Verde, A. T., and to proceed to Wilcox, A. T., for duty as Acting Medical Purveyor in the field. S. O. 107, Department of Arizona, September 17, 1881.

CUNNINGHAM, T. A., Capt. and Asst. Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 102, Department of the South, September 29, 1881.

GRAY, WILLIAM W., First Lieut. and Asst. Surgeon. Relieved from duty at Fort Canby, W. T., and assigned to duty at Fort Townsend, W. T. S. O. 135, C. S., Department of the Columbia.

---

THE BEAUTIFUL NURSERY conceit, that the sweet smile of the slumbering infant is caused by the whisper of an angel into its ear, is destroyed by the revelations of unemotional science. Dr. Charles Bell attributes the smile to reflex muscular action due to intestinal flatus, the rotation upward of the eyeballs and the tremulous movement of the lips being due to a far different cause than a communication from the unseen world.

## Medical Items and News.

SPONTANEOUS ANEURISM OF THE COMMON CAROTID CURED BY DIGITAL COMPRESSION. — In a Spanish journal, Sr. Parada Santin reports a case of spontaneous aneurism of the common carotid cured by digital compression. The tumor was situated in the region of the internal extremity of the clavicle, and measured six centimetres in length and four and a half in width, extending up as far as the lower border of the hyoid bone. The patient, a woman aged sixty-four, was placed under proper hygienic conditions and digital compression was exercised upon the artery between the sac and the heart. Becoming dexterous in this procedure, she practised it three times a day, at rising, at noon, and at night, for the space of a half-hour each time. At first the patient did not succeed in arresting the flow of blood through the sac, although the pulsation was rendered very feeble. Gradually the duration of the procedure and the number of times it was applied were increased, until at length the circulation of blood through the aneurism was arrested for six hours each day. At the end of four months the tumor had decreased in size by a centimetre in length and a half-centimetre in width; the impulse was feeble, the walls of the sac had not diminished in thickness, nor were coagula appreciated in its interior. A final recovery followed, only a slight increase in thickness of the walls of the carotid at the point affected indicating where the aneurism had been. The aneurism had been cured without the intervention of a clot, solely by the retraction of the three arterial tunics of the sac.

PREGNANCY AND CARIES OF THE TEETH.—During pregnancy many women suffer from caries of the teeth and dental neuralgia. The calcareous salts required for the development of the fetal skeleton must be supplied by means of an increased ingestion of these materials on the part of the mother; in default of this augmented consumption, the nutrition of the maternal bony tissues is affected and dental caries result. Many pregnant women have a morbid appetite for calcareous and other mineral substances. Preparations of calcium, especially the phosphate and hypophosphite, should, in view of the facts mentioned, be administered to enceinte females suffering from the above dental troubles.—(*Gazz. delle Clin.*)

A PSEUDO-PERICARDIAL FRICTION-SOUND. — The *Gazzeta Medica Italiana* mentions the following case: The patient was a man aged fifty-six, suffering from asthma and fatty degeneration of the heart. During exacerbations of his asthmatic attacks, a pericardial friction-sound was distinctly audible, and upon it was based the diagnosis of pericarditis. On necropsical examination the following was found: instead of pericarditis, only an old macula tendinea; the coronary arteries in a state of advanced atheroma and extremely hard and rough to the touch. It was supposed that these vessels, owing to their abnormal condition, had given rise to a sound simulating a pericardial friction-râle.

A CASE OF RIGHT HEMIGLOSSITIS.—In the *Sentido Catolico de las Ciencias Medicas*, Dr. Parella reports a case of right hemiglossitis. When first seen the patient was upon her knees in bed; she was cyanotic, and in imminent danger of asphyxia from me-

chanical obstruction to respiration. The right half of the tongue was increased to three or four times its normal size, the swelling extending to the submaxillary glands and the corresponding lymphatic ganglia. The pain experienced by the patient on the right side of the throat was intense. Several incisions having been made into the sublingual mucous membrane, a diminution in the size of the tongue, and some alleviation of the symptoms, followed. In view of this result, a dozen leeches were applied to the infra-hyoid region. In the afternoon the tongue had diminished considerably in size, and breathing was much more free. Twelve leeches were again applied, and the administration of wine and the application of warm cataplasms ordered. On the sixth day the affected organ had returned to its normal condition. The case is not alone interesting because only one-half of the tongue was involved, but also on account of the rapidity of the inflammatory process. The patient had gone to bed without any symptoms, and had been awakened at four o'clock in the morning, suffering as described. No cause could be ascribed for the phenomenon.

Increase of Mortality in Paris.—In 1877, the mortality in Paris was 23.89 in 1,000; but in 1880 it has increased to 28.90 in 1,000, a figure exceeding the death-rates of London and Brussels. This increase seems to have been due to the prevalence of typhoid fever, small-pox, and diphtheria.

Contributions to the Study of the Phenomenon of the Tendon Reflex.—In spinal epilepsy, when a patient in the sitting posture crosses one thigh over the other, we observe the phenomenon of convulsion or trepidation of the dependent foot, a to-and-fro movement of the extremity, sometimes propagated also to the opposite side. In a healthy person, sitting in the same position, a similar movement may be produced by striking the ligamentum patellæ. Professor Prevost's experiments in regard to the tendon reflex have yielded the following conclusions: 1st, sections of the spinal cord and nerve-roots in rabbits have proved that the integrity of the sixth pair of lumbar nerves (corresponding to the third or fourth lumbar pair in man), is necessary for the production of this phenomenon. 2d, a section made at the level of or a little above the emergence of the sixth pair of lumbar nerves, abolishes the phenomenon. 3d, anæmia of the spinal cord of the rabbit, produced by the compression of the aorta, modifies the phenomenon of the tendon reflex; after a few seconds' compression, it is exaggerated, but subsequently it diminishes progressively and disappears entirely after forty-five seconds. 4th, when the blood is again allowed to flow, the phenomenon reappears after an interval of time varying from a few seconds to a minute or more. The more thorough and the more prolonged compression has been, the more retarded will the return be. 5th, anæsthetics, if anæsthesia be profound, abolish the tendon reflex. The disappearance of the phenomenon during anæsthesia may be considered as a prodromatic symptom of collapse. 6th, the phenomenon of reflex tendon, as well as the epileptoid convulsion of the foot, is transmitted from the opposite side. This fact is well marked in animals whose spinal cord has been divided in the dorsal or dorso-lumbar region, a procedure which is followed by an exaggeration of certain reflex phenomena. These results have led Prevost to infer the spinal reflex nature of the tendon reflex.—(*Revue Méd. de la Suisse Romande.*)

An Infantile Neurosis.—Sr. Benavente, in the Spanish Academy, reports an interesting case of spasmodic salaam, or irritant spasm. The patient, a child, without any premonitory symptoms whatever, would suddenly nod his head in a violent manner, and fall to the ground unconscious. These attacks would last a few seconds, the patient rapidly returning to consciousness and continuing his play without any knowledge of the accident which had befallen him. Three of these attacks occurred in a half-hour. In this disease the patient sometimes falls forward, sometimes backward, sometimes to one side or the other. Its causes are congestion of the cord, and reflex phenomena due to worms or digestive disturbances. The treatment, consequently, should be antispasmodic, revulsive, purgative, or anthelmintic, according to the causal indications. In the case reported, the patient had been suffering from a scrofulide; a thapsia plaster was applied over the vertebral column, and the malady was completely cured as soon as the characteristic eruption appeared. The patient had had no attacks for three months.

The Oldest Inhabitant.—Joseph Martinho Coutinho, of Cape Frio, Province of Rio de Janeiro, Brazil, is reported to be nearly one hundred and ninety years of age, having been born, it is claimed, in 1694. He is said to be the ancestor of 42 children, 123 grandchildren, 80 great-grandchildren, and 20 great-great grandchildren. Like all those old gentlemen who have passed their first centennial, Senhor Coutinho undoubtedly gets up at four in the morning, delights in chopping wood by the cord, breaks in restive horses, walks twenty miles without the slightest fatigue, and is blessed with a fine appetite, good eyes, and the best of health. Born in 1694—George Washington's nurses will have to hide their diminished woolly heads.

An Insect the Cause of Epidemic Cholera Morbus.—In a communication to the *Union Médica* of Venezuela, Dr. Beauperthny, of the Universities of Paris and Caracas, asserts the cause of epidemic cholera morbus to be the sting of an insect belonging to the order hemiptera, class homoptera. Puncturing the skin of animals, the insect deposits its virus in the subcutaneous tissue. The puncture resembles that of a mosquito, and does not give rise to much pain. When the point affected is rubbed immediately after the introduction of the poison, and before the latter has been absorbed, livid greenish spots are produced similar to those resulting from the bite of venomous serpents. One sting of the insect is not sufficient to cause fatal results; the gravity of the disease varies according to the number of punctures made and their location. The author then points out the analogy existing between the symptoms resulting from the bite of venomous serpents and the symptoms of cholera morbus. Investigations begun in 1838, made in various localities and continued up to date, lead Dr. Beauperthny to assert that fevers depend upon a vegeto-animal virus, whose introduction into the body in the majority of cases is a true inoculation.

The Use of Electricity in Labor.—M. Apostili, in *Gazette des Hôpitaux*, from a total of five hundred electrizations of the uterus derives the following conclusions:

*First.*—That faradization of the uterus is entirely harmless.

*Second.*—Faradization is a uterine sedative.

*Third.*—Faradization abridges considerably the convalescence and accelerates the involution and retraction of the uterus. That it also hastens the restoration and promotes regularity of function.

*Fourth.*—Faradization guards the woman from the uterine complications of labor.

*Fifth.*—That faradization is the correct preventive treatment of uterine malpositions.

*Sixth.*—The action of faradization on the uterus is similar to that of ergot, only its action is more prompt and more energetic.

In conclusion, it is a marvellous therapeutic agent in obstetrics, simple in application, rapid and energetic in action, perfectly harmless, and can be interrupted or renewed at will.

It not only restores the uterus to the normal condition, but its use prevents further uterine complications.

PRELIMINARY EDUCATION.—At the sixty-first annual meeting of the Medical Society of Oswego County, held at the court-house in the city of Oswego, N. Y., the following resolutions were reported by Dr. C. M. Lee, to whom the matter had been referred, and adopted:

*Resolved*, That we, as a society and individually, will give no encouragement to, nor take into our office, any student with a less standard of literary acquirement than entrance examination to the sophomore year of an incorporated college, or that has passed the regents' advanced academic examination.

*Resolved*, A graduate of a normal school with three years' experience in teaching, with a knowledge of Latin to the sixth book of Virgil's Æneid, will be accepted in place thereof.

*Resolved*, That these resolutions be printed, and a copy sent to each county medical society in this State, to each member of this society, and to all gentlemen practising as physicians and surgeons of our school, so far as known.

*Resolved*, That a copy of this be sent to the MEDICAL RECORD for publication.

CHAS. R. LEE, *Secretary.*

[This is a move in the right direction, and is an excellent example for other county societies.—ED.]

SEPTICÆMIA RESULTING FROM A LEECH-BITE.—The *Gazz. Med. Ital.* quotes the following case: A Bernese had been suffering from toothache for several days, and to relieve it he followed out the advice of a dentist by applying a leech to the gum. Two hours later the pain increased, and the lip became the seat of an inflammation which extended to the cheek, neck, and breast. The following day the head was swollen, respiration was difficult, and the patient was in high fever. A few hours' later, he was attacked with delirium tremor, and convulsive vomiting. He died during the night of the second day, from septicæmia, as demonstrated by the autopsy. The leech-bite was larger than the ordinary, and its borders were black and gangrenous. A poison of unknown nature had evidently gained access to the system through this wound.

A NEW PHYSICAL SIGN OF ŒSOPHAGEAL STENOSIS.—In stenosis of the œsophagus, when the portion above the stricture was distended by gas, Dr. Feletti observed an unusual tympanitic sound upon percussing the front of the thorax. In order that he might be enabled to trace out the limits of the gastric region, he administered an effervescent powder to one of his patients; the gas, however, instead of distending the stomach, gave rise to an area of tympanitic sound over the sternum and as far as the left parasternal line. The fact that the bougie could not be passed down farther than thirty-five centimetres, together with the rejection of food and drink, indicated an obstruction, which was sufficient to arrest the downward passage of the gas. That this sound was not that of the stomach conveyed through the thorax was proved by a second experiment; a powder was again administered, but the thoracic sound was not developed, the gastric area of tympanitic sound being, however, well marked. At this time the patient was not suffering from vomiting. In other instances, Dr. Feletti succeeded either in rendering this chest-sound feebler and higher by drawing off some of the distending gas, or increasing the area by giving an effervescing powder.—*Gazz. Med. Ital.*

RECORD VS. RICORD.—Although this is not a journal of syphilography, one of our esteemed European contemporaries calls it the "Ricord."

PAIN CURED BY HYPODERMIC INJECTION OF PURE COLD WATER.—In the *Gaceta Medica* of Venezuela, Dr. Ponte relates his experiences in several instances in which he employed water hypodermically for the relief of pain. The first case was that of a boy who was suffering from an attack of intercostal neuralgia, so severe as almost to endanger the life of the patient by interference with respiration. Not having any morphine with him, the author determined to work upon the imagination of the sufferer by injecting pure cold water over the location of the pain, a procedure which, much to his astonishment, was followed by permanent relief. Impressed with this fact, Dr. Ponte resolved upon further experiments. The next case was one of toothache. In order to eliminate the imaginative element, he informed the patient of the treatment to be employed, for the execution of which permission was rather reluctantly given. An injection practised upon the side of the face nearest to the pain was followed by considerable ardor, but in less than a minute the odontalgia had subsided. Animated with these results, he employed cold water injections in a variety of different pains, always with happy issue, even in cases where morphine had been the drug previously administered. Another patient had been suffering nine years from intense gastro-intestinal neuralgia, which baffled all remedies. The pain came on after meals, and its violence was such as to cause her frequently to faint. When first seen by the writer, she was utterly prostrated. Two injections relieved the pain, and subsequent tonic treatment restored her to perfect health. Several hundred cases have been treated in the manner described, with good results. No explanation is given as to the action of the remedy.

PLEURISY ON THE LEFT SIDE, WITH EXUDATION, PULMONARY AND PLEURAL GANGRENE, ICHORÆMIA—COMPLETE CURE AFTER TWO OPERATIONS OF THORACENTESIS.—In the *Gazzeta Medica*, Dr. Zannini relates the following case: The patient, a lady aged forty, and of good constitution was attacked with pleurisy on September 20th. The attending physician regarded this as an ordinary cold, and the patient, after a few days' treatment, was allowed to go about. A week later she was forced to go to bed again, suffering from a cough which brought up nauseating sputa. Another practitioner, being called in, diagnosticated pleuritis, with effusion on the left side, and pulmonary gangrene. Under rational treatment the

patient improved, but on the 28th of October, a change for the worse took place. The face was bathed with a cold sweat, the features were pale and troubled, and the wandering eyes, cyanotic lips, and panting respiration, intermingled with sighs, expressed the anxiety provoked by the feeling of suffocation. The pulse was 150, respiration 60, temperature 104°. The left pleural cavity contained both gas and fluid. Thoracentesis was performed, and two litres of a foul-smelling, purulent liquid, intermingled with putrid shreds of fibrinous membrane, were removed. The canula was allowed to remain, and three times a day the pleural cavity was washed out with a two per cent. solution of carbolic acid. In addition to this, the patient was put under antiseptic and tonic treatment, alcohol, quinine, and cinchona being administered; vapor of turpentine inhalations were also advised. Under proper management a favorable progress was made. One day, however, during an injection of the solution, the lady was seized with alarming cough, accompanied by symptoms of suffocation, and the writer was astonished to see the injected fluid issue from the mouth, the gangrenous process having created a communication between the bronchi and the pleural cavity. A diminution of the quantity and the number of injections became necessary, on this account Upon two occasions the urine exhibited the characteristic olive tinge due to absorption into the system of carbolic acid, hence a hyposulphite solution was substituted. On November 16th, thoracentesis was agained performed, the patient having developed symptoms of septicæmia. More than half a litre of a greenish matter, intermingled with gangrenous shreds of lung, issued forth, emitting an intolerable stench. Antiseptic injections, the first one of which was attended by a vomiting of the solution, were again practised, and finally the fluid returned as clear as it entered. Subsequently the cavity became obliterated, and the patient recovered her health completely by the middle of May. The appetite and complexion are now good, the lady is well nourished, and not troubled by catarrh, cough, pain, or dyspnœa.

Varix an Hereditary Affection.—In the *Revista de Ciencias Médicas*, Dr. Morales alludes to a family in which a varicose condition of the veins seemed to be hereditary. A patient with this affection came under his observation, and, upon further examination, he found that her son, her sister, and a daughter of the latter, were suffering from the same condition. It furthermore appeared that the mother of the patient and another sister, both deceased, had also had varices. The writer thinks that a recognition of the hereditary element in the disease may lead to a discarding of operative procedures.

Troubles of the County Society in Regulating the Practice of Medicine.—The Chairman of the Board of Censors of the County Medical Society, Dr. Mundé, has written to the various daily papers, calling attention to the difficulties met with in attempting to enforce the law regulating the practice of medicine.

The chief obstacle is the indifference of the Grand Jury. This body several times has refused to bring indictments, when every evidence that the law had been violated was presented. Several persons who have been arrested have been let off and are now practising medicine again.

Tetanus in Baltimore prevailed so extensively during July and August as to have almost the character of an epidemic, Twenty-six deaths from it were reported during the period between June 30th and August 3d. In addition, there were five deaths from trismus nascentium. The source of the wound was, in most cases, toy pistols, and the seat of injury, as a rule, on the hand.

The cases of tetanus during this period nearly all ended fatally. Various forms of treatment were tried, among them nerve-stretching, but not often with success. In the case where the nerve was stretched, the symptoms improved temporarily, but the patient eventually died.

There were no unusual meteorological conditions to account for this prevalence and malignity of tetanus. The editor of the *Maryland Medical Journal* has furnished some interesting preliminary studies regarding it.

Death of Dr. Robert McIlvain.—Dr. McIlvain died in this city recently, of cancer of the stomach. He was educated in this country and in Paris, studying for a time under Claude Bernard. He lived in Ohio for a number of years; then came to New York. He was well known to the profession here both for his professional knowledge and social qualities. He was especially remarkable for his memory, and his remarks at society meetings always excited much attention from the earnest manner in which he would roll off facts and figures on every subject.

Tri-State Medical Society.—The seventh annual meeting of the Indiana, Illinois, and Kentucky Tri-State Medical Society, will be held in the city of St. Louis, Mo., Tuesday, Wednesday, and Thursday, October 25, 26, and 27, 1881. The profession of the "Mississippi Valley" are cordially invited to attend.

Dr. Tanner has been reported dead; but later accounts state that he is living and preparing for a fifty-day fast.

A New Medical School has been organized at London, Ont. The Canada *Lancet* says of the promoters: "They will find it, however, no bed of roses (even under the most favorable circumstances), no sinecure, no crown of glory, but plenty of drudgery and very little for it. We speak from nearly twenty years' experience in connection with a comparatively successful medical school."

Koumiss and Maltine.—Maltine added to koumiss is said by Dr. C. N. Fowler to make a more palatable and nutritious mixture than either separately.—*Cincinnati Lancet.*

Obstetric Aphorisms.—Dr. H. Webster Jones, of Chicago, as Chairman of the Committee on Obstetrics, closed his report to the Illinois State Medical Society, with the following valuable and suggestive sayings. With these as his guide, the practice of the obstetrician of to-day would furnish less work for the gynecologist: 1, an intelligent confidence once established between patient and physician does much to banish the terrors of the lying-in room; 2, it is possible to foresee and prevent the occurrence of the almost fatal form of eclampsia gravidarum; 3, cleanliness is especially next to godliness in the case of the accoucheur, its absence renders one liable to professional homicide; 4, the modern midwifery must not be meddlesome, but must be mediatorial in the sense of palliating suffering, expediting nature's processes by well-proven means, and removing scientifically all inexplicable, accidental, or morbid states and conditions—idleness is no longer an approved qualification for a degree of obstetrics; 5, the hand is the best uterine dilator; 6, the forceps

should never be employed until the os uteri is dilated or dilatable, and then not unless the membranes have been ruptured, and labor delayed unnaturally for at least an hour; every practitioner should become skilful in their use, and they should never be left at home for fear of temptation; 7, unnecessary and avoidable delays in labor are fruitful sources of gynecological practice, they promote inflammation and sepsis; 8, the patient's hopeful confidence, and the physician's industrious attention, actually contribute to the physiological elements of labor; anæsthetics here are, to say the least, superfluous; 9, bimanual aid in effecting the deliverance of the placenta is not only proper, but advisable; skilfully rendered, the cry of "uterine inversion" becomes no longer a bug-bear; 10, the continuous and intelligent counter-pressure over the fundus uteri during the child's exit, the delivery of the placenta and the period of frequent oscillation, be that a shorter or a longer time, is a safeguard never to be neglected; 11, pursuant to the same end, the application of the bandage, and its continuance, as long as the uterine globe can be felt and embraced by it above the pubis, contributes not only to comfort, but to speedy involution; after the seventh day, close pressure must be interdicted; 12, puffiness of one ankle, with tenderness of the corresponding groin, and an abnormally quickened pulse, with or without copious sweating, noticed within the first ten days after labor, betoken the presence of phlebitis, and the possibility of embolism or thrombus, and resultant sudden death; 13, the duties of an obstetrician are not concluded until a careful examination, from six to eight weeks after parturition, proves the integrity of the organs involved.

Renal Cylinders and Cylindroids.—Dr. Vincentini divides these bodies into two groups: the first comprises those which offer a more or less easily discernible filamentous structure, and includes the elementary or fibrinoid filament, the cylindroid, which gradually passes into the compact cylindroid, and, through intermediate forms, into the apparently homogeneous hyaline cylinder. The second series includes those products which are homogeneous in structure, and embraces hyaline and waxy cylinders.

According to the author the cylindroids and their allied forms originate from a pathological secretion of the tubular epithelium, analogous to that of a mild catarrh; hyaline cylinders from a secretion analogous to that of a more intense catarrh. Doubt exists as to the origin of the waxy cylinders; they may either consist of the broken-down epithelium of the tubuli, or of that of the Malpighian glomeruli. The latter view, that of Langhans, the author combats.

Case of Acute Chorea—Treatment with Veratrum Viride.—Dr. B. F. Gary, of Abbeville, S. C., in the "Transactions of the South Carolina Medical Association, 1881," reports the following case: F. B——, while at college the past winter, suffered from a very severe attack of acute rheumatism, and while convalescing from this disease, and when it was supposed he was nearly well, irregular movements of the muscles, so characteristic of chorea, were noticed. At first these movements were confined to the left side, but as the disease advanced they became general. He was put upon the most approved treatment—such as iron tonics, oxide of zinc, chloral, arsenic, cimicifuga, racemosa, etc. No benefit was derived from the administration of these remedies, and as the symptoms were becoming more aggravated, such as difficult deglutition, the drawing of the mouth to one side, the rolling of the eyes in various directions, flushed face, pain in the head, constant movement of the hands and feet, quick pulse, etc., threatening a fatal termination from congestion of the brain, it was determined to put him upon large doses of veratrum viride, ten drops every two hours, increasing two drops each dose until nausea or a considerable reduction of the pulse should be observed.

Just after the administration of the fourth dose of eighteen drops, there was free emesis, and a reduction of the pulse to fifty beats, with great prostration; this, however, under a dose of stimulants, soon passed off, when it was observed that there was great improvement in the choreic movements, which just before had been so violent and serious. This treatment was continued in smaller doses, increasing the quantity in proportion to the movements induced by the chorea. The case continued to improve daily, and at the end of two months was dismissed, cured.

Borate of Chinoidine—A New Febrifuge Proposed by Dr. De Ury.—Considering the current opinions in regard to the causes of paludal fevers and the antiseptic properties of boracic acid, Dr. De Ury thinks that the combination of this acid with the amorphous alkaloid cinchonoidine may prove a valuable acquisition in the treatment of malarial fevers in the place of the much more expensive sulphate of quinine, the price of the former remedy being less than one-twelfth that of the latter. A gramme of the borate of cinchonoidine is equivalent in its effects to 66 centigrammes of the sulphate of quinine.—*Gaz. Med. di Roma.*

Ditana Digitifolia.—With this plant, a native of Brazil, Prota-Giurleo (*Il Farmacista Italiano*, 1881), experimented upon nursing women. It was found that under the administration of ditana digitifolia, either in the form of an aqueous infusion or an ethereo-alcoholic tincture, milk could be made to flow from the mammæ upon the slightest pressure. The drug has a selective influence over the mammary glands. It promotes, increases, accelerates, and even brings back the lactic secretion. The author has prepared a liqueur named the "Galattofero," which is readily administered to mothers and nurses. Of this tincture one to three tablespoonfuls are added to half a litre of water, or, better, to infusion of chamomile, and thus taken in divided doses during the day. The remedy is recommended in cases of mothers and nurses whose milk is scanty, and nurses in maternity hospitals, who are compelled to suckle several children.—*Riv. Clin. di Bologna.*

Phosphate of Bismuth.—Tenedat (*Bull. Gén. de Thér.*, 1881), by reason of the extreme variability in composition of the commercial nitrate of bismuth, proposes to substitute the phosphate of bismuth for the subnitrate. The dose of the phosphate is less (one to two grammes), and it may be employed under the same circumstances. To prepare it, phosphate of sodium is dissolved in distilled water, and this raised to the boiling point in a glass or porcelain vessel; to the boiling solution acid nitrate of bismuth is added, a little at a time; the reaction begins immediately, and after a protracted boiling the phosphate of bismuth is precipitated in the form of a white, dense granular powder, which readily separates from the acid liquid. It is washed upon a filter until the filtered fluid exhibits a neutral reaction, and is then dried.

# Original Lectures.

## FOREIGN BODIES ON THE CONJUNCTIVA OR CORNEA.

A Lecture Delivered in the University of the City of New York.

By D. B. ST. JOHN ROOSA, M.D., LL.D.,

Professor of Ophthalmology.

Gentlemen: I shall to-day deviate somewhat from my usual custom, and lecture on a subject which I am unable to illustrate by actual cases. I have selected the subject because it is one of the topics of which the general practitioner should have a certain amount of positive knowledge. The subject of the present lecture is foreign bodies in the conjunctiva, or upon the cornea, not foreign bodies *in* the eyeball, but foreign bodies *on* the eyeball, or under the eyelids. When we come to consider the subject of foreign bodies within the eyeball, we shall have reached one which is so serious that the general practitioner, unless he be a surgeon who has given some special attention to diseases of the eye, is not able to grapple with it successfully. It is an important subject of itself, and I have already, in a general way, lectured upon it.

The questions upon which I propose to speak now, belong among those with which every general practitioner should be thoroughly familiar. This subject may be the very first to engage his attention. The next time he rides in a railway carriage, or goes within range of the droppings from the elevated railway, or walks about in the dust which a March wind whirls in the streets of a city, he may become the subject of such an accident, or he may be called upon to relieve one who has been subjected to a like exposure. It is a question which may come to the young general practitioner in the very first hours of his practice. Some farmer may come to him from the field, upon whose cornea there has lodged a beard of grain; or some child may be brought who has been climbing a tree, and there has dropped into the conjunctival sac a bit of bark, or twig, or a bud.

The subject is a practical one. Ophthalmologists are sometimes regarded as unpractical people. We are thought to be men who deal with mysterious signs, + and −, and "V equals $\frac{20}{40}$," etc., and other profound subjects, which you have had occasion to study with me. For the instant, we may admit that the ophthalmologist says much which is abstruse and obscure, and which the general practitioner may dismiss from his mind at once with a reasonable degree of propriety; but here is a subject which he cannot dismiss.

The conjunctiva, as it lines the eyelids and is reflected over the eyeball, forms two sacs. [The reflections of the conjunctiva were illustrated upon the blackboard.] A foreign body getting into the upper conjunctival sac is much more likely to escape observation, and is much more difficult to remove, than when one gets into the lower conjunctival sac. The lower one is readily everted, and how easily it takes on inflammatory conditions has been shown in a previous lecture.*

* See Medical Record, vol. xix., p. 398.

It is stated by competent authority (Dr. Loring), that the lower conjunctival sac, in a very large proportion of the people living in this city, is now hyperæmic, on account of causes concerning which we have recently heard a great deal. We know that this portion of the eye is much more readily reached by foreign bodies than any other, and, on the other hand, a foreign body lodging there is very easily removed. So there are advantages, as well as disadvantages attending this anatomical condition of things. But when we reach the upper conjunctival sac, we have to deal with a part which requires a trained hand in order to expose it fully. I have already taught you how to evert the eyelid. You know that it requires some dexterity and a little practice in order to be able to evert the upper lid properly, so as to expose the upper conjunctival sac completely. Yet it may be the first surgical manœuvre which you will be called upon to perform. If you are unable to do so properly and readily, and remove the foreign body, and thus give your patient relief, you are at once exposed to the risk of being regarded as an incompetent practitioner. We will dismiss the lower sac, because any one of you is competent to remove a foreign body from it; for you have simply to pull the lid down and readily remove, with a handkerchief stretched over a finger, any foreign body which has not actually become imbedded in the conjunctiva or tissues beneath it.

But such foreign bodies as clippings of steel, particles of sand, or of coal, seeds, and so forth, may get into the upper conjunctival sac. A foreign body which very frequently enters the eye is a cinder from a locomotive. There are some curious cases belonging to this class of foreign bodies in the conjunctival sac. I was once called to an asylum for the insane, to remove bits of straw from the upper conjunctival sac which the patient had put into her own eyes.

Even large particles may enter the upper sac without suspicion. I have always remembered the case of one of my colleagues—Dr. Hackley, at the N. Y. Eye and Ear Infirmary—in which he found a small splinter of wood, that had been there probably for years, and caused chronic conjunctival inflammation.

I also recollect a case to which I alluded in my prefatory remarks—that of a child—who was brought to me from a neighboring town, said to be suffering from conjunctival catarrh; and indeed it was suffering from a very severe inflammation of the conjunctiva. But one very noticeable feature of the case was that the inflammation was limited to one eye. This, of itself, was a suspicious circumstance. Diseases like catarrhal conjunctivitis usually affect both eyes at the same time; but in this case one eye was perfectly sound, while the conjunctiva of the other was intensely inflamed. It is not a suspicious circumstance to find one eye perfectly healthy and the cornea of the opposite eye inflamed. It is not suspicious to find one sclera inflamed and the other healthy, nor is it peculiar to find one retina or one lens the seat of disease, while the same structures in the fellow eye are normal; but it is suspicious to find the *conjunctiva* of only one eye affected, and it should immediately arouse the suspicion that some local cause is producing the inflammation.

This little girl was being treated for conjunctival catarrh, and the most energetic measures had been resorted to; yet, despite all this, perhaps on account of it, the eye became no better, but decidedly worse.

Following the routine plan which every practitioner should follow in treating diseases of the eye, I examined everything connected with the organ which possibly, not probably, might explain the cause of such a condition. I everted the upper eyelid, not without difficulty and objection on the part of the father and the mother—one of the obstacles with which you will have to contend—and I found a very small bud from a cherry-tree, up and down which this child had been climbing, and there was the *fons et origo* of the conjunctival catarrh for which it had been so vigorously but unsuccessfully treated. All that was necessary was to remove the foreign body and allow nature to cure the case.

This child had been treated so assiduously that it had received internal remedies for some length of time. And now need I tell you that it is worth your while to learn how to evert the upper eyelid? How shall it be done, and how many of you are able to do it? When you begin to practice, neglect no precaution or care which will enable you to surely perform the operation you undertake. Remember that if you fail, you will not only lose your own confidence, to retain which constitutes nineteen-twentieths of the battle, but you will soon excite the suspicion that the young practitioner from New York is not so thoroughly qualified as it was hoped he would be found to be.

In the first place, the patient, so far as possible, should be in a comfortable position. He may be seated in a chair with the head well supported. With a foreign body in the conjunctival sac the patient is in distress, and his eyeball is not entirely under his control. He is not as able to respond to your requests as to where he should look as though it were not there. Get the head, therefore, properly supported, and then with the thumb press the integument of the lid against the eyebrow, so as to put it upon the stretch, and tell the patient to look down—not to turn the head down, but to turn the eyes down. Then catch the eyelashes and edge of the lid with the fingers of the other hand and turn the lid quickly over the thumb; in the meantime the patient looks down constantly. You see how readily, by this simple manipulation, I have succeeded in exposing our friend's conjunctiva, which we find to be hyperæmic in a marked degree, and yet, unless you have practised these movements somewhat, you will be mortified when you make your first attempt to perform this simple operation with lookers-on around you. An intelligent assistant will be of advantage, and there is scarcely any place in which you cannot secure one to hold the head, and his determination must be that the patient shall not turn his head down, but shall look down, and thus turn the eyes downward.

Next, how are you to remove the foreign body after you have found it? How shall you get rid of that little black speck which has been the cause of so much discomfort to the patient—which, perhaps, has given him a very uncomfortable night, has concentrated all his attention, and almost led him to curse railroad carriages? It is usually a simple matter after having everted the lid, but there is method even here. If it is a lady who has thus been selected, she will have her own handkerchief in her pocket, and she will feel better satisfied if you will use that rather than your towel, for she will not feel sure that the towel is clean, while she knows that the handkerchief is.

Remove the foreign body with the handkerchief then, and *do not throw it away*. Show it to the patient, and be sure that he or she recognizes it—and why? The little shallow depression which that foreign body made in the conjunctiva will give a sensation of discomfort, and sometimes, not always, give rise to the same symptoms that existed before the foreign body was removed. It is well, under such circumstances, to have the proof of what you have done, lest the patient say, "He said he took it out. I paid him for removing it, but I know that it is in there yet."

In the majority of cases, however, the feeling of comfort is so great, the relief is so instantaneous, that there is no occasion for such unpleasant complaint.

You will seldom need any instrument for removing a foreign body from the conjunctival sac, beyond the hands and a delicate piece of cambric or a smooth, well-worn towel. The patients very seldom need any after treatment. It is well to direct that the eye be bathed with warm or cold water, and protected from dust, and the blood-vessels will soon return to their normal condition. I should mention that occasionally a patient will return, insisting that a foreign body is in the eye, when there is none there. A few evenings since, a medical gentleman came to me, saying, "I have something in my eye, and I am suffering very much. My friend, Dr. ——, says there is nothing in it, but I know that there is." But I was unable to find it, and the man's indignation was very great, and he exclaimed, "I know it is there, for I feel it." I then examined his eye very carefully again, after which I said to him, "You may be certain that there is no foreign body in your eye." I first examined his eye by the aid of ordinary light, but when he was so positive with reference to the presence of the foreign body, I took him to a gas-light and with a two-inch lens, threw the concentrated rays into his eye, and examined the entire conjunctival space, and then I was able to answer him in the most assuring manner. What was the cause of his sensations? An attack of conjunctival catarrh was beginning. Many of those cases begin very suddenly, as though something struck or entered the eye, and you must not be deceived and take it for granted that there is a foreign body in the conjunctival sac simply because a patient has a sensation as though some rough substance is pressing upon the cornea.

### FOREIGN BODIES ON OR IN THE CORNEA.

There are some foreign bodies which seem specially prone to strike the cornea if they enter the eye, and one very apt to get there, and particularly dangerous, is a bit of gun-cap. These particles sometimes enter the cornea and may be buried deeply among its layers. Then the ordinary filings from machinery may fly and strike the cornea and be buried in its tissue. Usually, however, these bodies lodge in the epithelial layer. The question of course at once arises, when a case of this kind presents itself, Where is the foreign body? If it has entered the eyeball, an accident has occurred upon which we do not at this time propose to speak. When it lies on the cornea its removal is very simple. The mode of procedure is:

*First.*—Secure the head of the patient as I have just instructed you.

*Second.*—Hold the eyelid against the ball, so as to fix it, with the left hand.

*Third.*—With the other, by means of a delicate blunt bit of steel in a handle, tilt the foreign body off the cornea.

Instead of using your fingers to steady the eyeball, you may find an ophthalmostat, invented by

Dr. Townsend, of New Haven, very useful. I show you the instrument. A very good one may be extemporized of wire, and this is the one Dr. Townsend first used. As you see, it is a simple ring, which presses on the eyelids and holds them apart and against the ball.

Do not think, however, that the spud is essential to the proper removal of this particle. A bit of wire, the head of a pin, or even a piece of wood will answer very well. A simple pushing motion against the foreign body will shove it into the conjunctival sac, from whence it can be readily removed, or it is lifted off entirely by the spud, and the operation is performed.

But suppose the foreign body has found its way into the epithelium and is actually lying there, what then? In the first place you must now have a good light. These particles are sometimes very small, and accurate examination is required in order to determine whether or not a foreign body is present, and exactly where it is situated. Sometimes the beginner is misled with regard to the appearance of the foreign body—especially if he has been told that one is there —by the black spots upon the iris, which are seen through the perfectly transparent cornea.

First, then, have a good light; and, next, determine there is a foreign body there, and locate the position. If the body is small, aid yourself with a double convex lens. Then take an ordinary spud, or cataract-needle, and proceed to scrape away the epithelium until you reach the foreign body and lift it out of its position. This operation will be somewhat painful, and in order that you have free access to the eyeball it may be necessary to use an instrument for holding the lids apart.

There are no exigencies equal to those encountered in a country practice, and the ready wit which comes from a first-class country physician is not infrequently essential for such an operation as this.

The epithelium of the cornea is sensitive; it is the painful part; it is well supplied with nerves, but after removing the foreign body you can scrape without causing much pain. But suppose it has gone further; suppose it has passed through the layers of the cornea, and you apprehend that it has either entered the anterior chamber, or that if you pick at it much it will drop in there; what shall be done then? Here you reach the boundary line between the general practitioner and the surgeon and the specialist. If you are a physician, and not a surgeon, you had better let these cases alone or get some one to assist you. If the foreign body is so far imbedded in the cornea as to be in danger of dropping into the anterior chamber, it is a matter with which only a good surgeon should meddle. How should he interfere? He may often remove the foreign body without entering the eyeball; but only by using the most delicately constructed forceps, handled with a most steady hand, and the manipulation should be done with the patient under ether. But suppose that the surgeon becomes convinced that he cannot remove it without entering the eyeball, how shall he then proceed? I think Dr. Agnew's method is the only one worthy of consideration, and that consists in passing a Beer's knife through the cornea behind the foreign body. The knife thus passed in forms a bed upon which you may safely work. But these are rare cases, and ordinarily no harm will come from waiting until the assistance of a surgeon can be secured. After the foreign body has been removed, the eye should be treated as if it had undergone a considerable operation.

In my prefatory remarks, I made allusion to the fact that perhaps you would be called upon to remove a wheat-beard from the eye of a farmer. That was no fancy picture. A farmer came to me, not many years ago, with an eye which had been inflamed for a number of months. It had been subjected faithfully to medical treatment, but it did not get well. The diagnosis of inflammation of the cornea had been made, and correctly; but it was a case of a foreign body in the cornea which had set up the inflammation, and that being removed, the disease which had existed for months disappeared within two or three days. Now imagine the feelings of my friend, who had seen the case several times, and had not examined the eye with reference to the presence of a foreign body. We learn a great deal by our mistakes, but we wish to learn as little as possible in that manner. We wish to make as few errors as possible. Do the best we can, we shall overlook much, but great care will cause us to avoid passing over those things which are obvious, and thus becoming superficial as well as general practitioners.

Therefore it is that I have spent so much time upon what may seem to be an unimportant subject, foreign bodies in the conjunctiva and on the cornea. It is not so important a subject with regard to sight as foreign bodies within the eyeball, but it is important in the sense that the knowledge which enables you to diagnosticate and remove them will afford your patients and you the greatest satisfaction, that of being relieved from and of having relieved great discomfort, or even distress.

---

The Rapidity of Peripheral and Central Nerve-Impulses.—The rapidity of nerve-impulses has been quite accurately measured, and has long been well known. Hirsch's experiments are also quite familiar, in which he showed that a touch on the face was recognized by the brain, and responded to by a manual signal, in the seventh of a second; also that the speed of sense differed for different organs, the sense of hearing being responded to in the sixth of a second; while that of sight required only one-fifth second to be felt and signalled. In all these cases the distance traversed was about the same, so the inference is that images travel more slowly than sounds or touch. It has still remained, however, to show the portion of this interval taken up by the action of the brain. Professor Donders, by a very delicate apparatus, has demonstrated this to be about seventy-five thousandths of a second. Of the whole interval, forty thousandths are occupied in the simple act of recognition, and thirty-five thousandths for the act of willing a response. When two irritants were caused to operate on the same sense, one twenty-fifth of a second was required for the person to recognize which was the first; but a slightly longer interval was required to determine the priority in the case of the other senses. These results were obtained from a middle-aged man, but in youths the mental operations are somewhat quicker than in the adult. The average of many experiments proved that a simple thought occupies one-fortieth of a second.

The Sanitary Condition of the White House is not so bad as has been supposed. So says Col. G. E. Waring, who has recently made an examination of the place.

## SANITARY ADMINISTRATION AND THE HYPOTHESIS OF EVOLUTION.

By HENRY M. LYMAN, A.M., M.D.,

PROFESSOR OF PHYSIOLOGY AND OF DISEASES OF THE NERVOUS SYSTEM, RUSH MEDICAL COLLEGE, CHICAGO, ILL.

### Part II.

Dr. Chaillé enters a strenuous objection against the doctrine that there is such a thing as hereditary tolerance of disease consequent upon ancestral experience of disease. This objection he bases upon the statement that authors like Prichard, Elam, Ribot, Spencer, Darwin, and Holland have not been able to present any proofs of hereditary resistance to disease. But this is not surprising, since the subject is new to the minds of men, and little, if any, of the evidence in favor of this belief had been collected when those authors wrote. However, this forms a matter of little importance, since Dr. Chaillé virtually abandons the field in a confused little foot-note (p. 143), in which he admits that "survival of the fittest influences, of course, the results of continued exposure to disease." This is all that I have claimed. It is through the survival of the fittest among the component cells of the body that a sufferer from small-pox acquires his future tolerance of small-pox virus. It is the hereditary transmission of this quality to the immediate descendants of those surviving cells that sustains this tolerance during the lifetime of such an individual. As Ribot says, such "acquired modifications can certainly be transmitted" in a qualified degree to the offspring. If that offspring, again, be subjected to the same process of natural selection among the elements of its tissues, the further modification must proceed indefinitely. In this way the living body becomes adjusted to its environment. It is in this way that we may partly account for that slow, secular evolution of disease-types in the human race which has puzzled so many observers who have remarked the appearance, course, and disappearance of diseases during the progress of time.

As evidence of the consequences of such a process of natural selection producing hereditary tolerance of disease, I would again call attention to the history of small-pox as observed among the English and Americans. At the commencement of the present century the operation of natural selection had evolved a tolerance of small-pox represented by a mortality which seldom reached 20 per cent. of the cases. Copland gives the following figures from the statistics of the disease in Boston during the last century. During the epidemic of 1721 the ratio per cent. in *natural* small-pox, excluding all inoculated cases, was 14.8; in 1730 it was 13.5; in 1752 it was 9.7; in 1764 it was 18.5; in 1776 it was 9.5; in 1778, during the Revolutionary war, it was 34.4; in 1792 it again fell to 14.2. I have not access to English statistics for the same period, but as Boston was then to all intents and purposes an English settlement, it is hardly probable that there was any special difference between the experience of the two branches of the same race at that time.

If now we examine the statistics of mortality in the London small-pox hospitals during the present century (Cameron: *The Fortnightly Review*, p. 599, May, 1881), we learn that the mortality from small-pox in unvaccinated persons exhibited the following ratios: From 1836 to 1851 the ratio per cent. was 37.5; from 1852 to 1867, during which time great improvements in hospital accommodation were effected, the ratio was 35.7; from 1870 to 1879 the ratio was 44.6. This increasing mortality, characterized by a considerable increase in the hemorrhagic form of the disease, has taken place in spite of all the vaunted sanitary improvements of the present day. At the same time the protection afforded by vaccination has diminished. In London, where vaccination with human lymph has been so long and so faithfully performed, the registers of the small-pox hospitals (*loc. cit.*) indicate an increasing mortality from post-vaccinal small-pox. During the early years of the century the ratio of mortality in such cases, though presenting four or more good vaccine scars, was less than one per cent. From 1836 to 1851 it was 1.1 per cent; from 1852 to 1867 it was 2 per cent; from 1870 to 1879 it was 4.83 per cent.

Facts like these admit but one explanation. Our population is losing that power of resistance to small-pox which it had acquired through the operation of natural selection. As a consequence of that tendency to revert to original types which is characteristic of all living organisms, our people are gradually falling back into the condition which they occupied before their first experience of small-pox. What that condition was may be learned by a perusal of the history of the ages during which the dreaded disease first made its way from the East into Europe. Since then the same dreadful fatality has attended its first invasion of the American Indian tribes, the Africans, and the Pacific Islanders. It is usual to explain the terrible ravages which were created by small-pox among these people by saying that it is a disease which is very fatal to the dark-skinned races. But this is no explanation at all. Nor will it satisfy the conditions of the problem to say that the dark-skinned races are scorbutic, or scrofulous, or underfed, or generally feeble. Many of them rank among the most vigorous and athletic people in the world. Of course, no one claims any single cause for such a rate of mortality as that which marked the destruction of the American Indians. But one of the principal causes of the difference between these dark-skinned races and their European brethren lies in the fact that these last had been for a thousand years subjected to the operation of natural selection against small-pox before the process was commenced in America or Africa. The consequently differing degree of hereditary tolerance is approximately indicated by the statistical table of Boston (Copland, *loc. cit.*). When, in 1752, the ratio of mortality from small-pox was 9.2 per cent. among the whites, it was 14.2 among the colored inhabitants of the city, even though they were not all fresh from Africa. In this respect small-pox—a disease of the temperate zone—treats the tropical populations just as yellow fever—a tropical disease—treats the inhabitants of the extra-tropical world. But that this is not a mere question of climate is shown by the fact that yellow-fever is quite as fatal within the tropics as elsewhere, if carried beyond its endemic focus, while some of the most frightful examples of mortality from small-pox have been furnished by the Indians of Canada and of the Northern United States. That this mortality among the Indians was not a mere matter of complexion is shown by the fact that at the present time among their dark-skinned descendants, the Mexican Indians,

after nearly four hundred years of experience with natural small-pox, it is not considered a formidable disease. That it was not the result of bad hygiene is shown by the present experience of the same unhygienic people. Exact figures are wanting, but it is probable that they are now quite as tolerant of the disease as were the Bostonians during the last century.

The experience of mankind with syphilis illustrates all that I have claimed for the evolution of a hereditary tolerance through natural selection. All intelligent writers admit the accuracy of the general conclusions reached by Dr. Charles L. Dana in his essay on the "Benignity of Syphilis among Seamen." It is unnecessary to multiply illustrations upon this point.

Measles also furnish an instructive lesson in this connection. This disease is endemic in the temperate regions of Europe and America. Generations unnumbered have experienced the action of its poison, until a degree of tolerance has been evolved by the action of natural selection and heredity, which is represented by a death-rate which at the highest estimate seldom reaches seven or eight per cent. What the death-rate may have been in ancient times it is impossible to ascertain, because in those days measles was confounded with small-pox. If at that time more fatal than at present, such confusion is not at all surprising. Coming down to modern times, and excluding all unusually fatal local epidemics which have occurred under exceptional circumstances among people long habituated to the disease, we find that the invasion of a virgin population by measles is uniformly attended by a remarkable mortality. Dr. Chaillé seems inclined to doubt my statement that the Sandwich Islanders were decimated by measles in 1848. What will he say to the history of measles along the Amazon in 1749–50 ("Ziemssen's Cyclopædia," vol. ii., p. 114), when 30,000 people died out of the scanty Indian population? Or what shall be said of the mortality at the Fiji Islands, in 1877, when 20,000 perished out of a population of little more than 100,000 ("Ziemssen Supplement," p. 104)? It will not suffice to ascribe this mortality to the fact that these were dark-skinned people, for among the Japanese—a nearly white race—we are told (THE MEDICAL RECORD, p. 91, January 22, 1881,) that in 1861, after an immunity lasting for twenty-seven years, measles "swept from one end of the empire to the other in a few weeks," attacking all who had not previously experienced the disease, being nearly half of the 35,000,000 of inhabitants, and causing a mortality which may be inferred from the fact that in the city of Yedo there were 75,000 deaths out of a population of 1,500,000. Catastrophes like these attest the value not only of ancestral experience of measles, but of continuous adjustment to its poison. Even among people who, by reason of the severity of their ordinary struggle for existence, have become, like the Faroe Islanders, remarkably tolerant of all the ordinary causes that militate against vital existence, long immunity from measles greatly increases the mortality which accompanies a renewal of acquaintance with the disease. To say nothing of the fatality of disease under such circumstances, no one who has not witnessed such an epidemic can form any idea of the universal distress which obtains during its prevalence. Far better the diluted misery which attends the sporadic diffusion of the disease as we experience it upon our continents. The experience of the Japanese in this particular furnishes an admirable illustration of the dangers that attend a state of isolation. It is like balancing a pyramid upon its apex—the slightest disturbance is sufficient to accomplish the most frightful overthrow.*

The history of scarlet fever is also replete with instruction in this respect. Evidently we know nothing regarding its earlier prevalence in Europe, when, with measles, it was confounded either with small-pox or with the plague. The remarkably plastic character of its virus, by virtue of which its intensity is more easily varied than that of almost any other disease, renders it very difficult to assign an exact valuation to each of the various causes of the special malignancy or benignity of any particular epidemic. It is worthy of remark that formerly it was not considered a dangerous disease among the English. Sydenham ranked it as a benign disease. When it invades the tropics at the present time it is seldom fatal, and soon becomes extinct. But when it first appeared in this country, in 1735, its fatality was most alarming. Copland records the fact that "its progress was very slow, but very fatal. Villages were depopulated by it, and parents had to bewail the loss of all their children." In this record we see the disadvantages of isolation—long immunity, loss of resistance, great mortality. The same thing was illustrated at the Cape of Good Hope (*Medical Times and Gazette*, p. 535, November 20, 1858), when, after absence of scarlet fever for about twenty-five years, "out of the number of persons attacked, many of whom had arrived at adult age, nearly one-third died." Such a high rate of mortality after long immunity is not, however, invariably observed. At Stuttgart, for example ("Ziemssen's Cyclopædia," vol. ii., p. 292), "after 1830 scarlet fever disappeared entirely, and the first epidemic which at length appeared was in 1846, and there were no fatal cases." So variable is the intensity of the poison of scarlet fever that this favorable experience might easily be explained by the hypothesis of accidental causes, favoring attenuation of the virus, or producing increase of vital resistance among the people, without resorting to the supposition that this experience is opposed to what has been so often observed elsewhere. But, without a full history of such an epidemic, it cannot be allowed to count on either side of the question.

When we review the history of scarlet fever in any particular locality, we find that it usually presents a succession of benign epidemics, followed at length by a malignant epidemic. This again is succeeded usually by another series of benign epidemics, and so on indefinitely. Here, again, we may remark the operation of the law of natural selection and heredity. A succession of benign epidemics implies a growing class of individuals who have not experienced the disease in their own persons or in the persons of their immediate progenitors. Hence increased susceptibility to the disease, until finally the pyramid

* Dr. Chaillé is the author of the following amusing syllogism, which he has attempted to father upon me:

"The vaccine poison is attenuated small-pox poison, but instead of causing, it arrests a spreading disease, namely, small-pox—therefore, this attenuated poison should be as widely diffused as possible; *hence*, the measles poison, which is not attenuated and does not arrest, but in fact causes a spreading disease, namely, measles, should be as widely diffused as possible, and *thereby* be attenuated."

The evidence regarding the paternity of this monstrosity is too clear to permit my acceptance of the imputed relationship, even if I were as complaisant as Monsieur Gillenormand himself. What I did teach was this: Since we avoid the perils of unmitigated small-pox by experience of its mitigated form through vaccination, it would be well could we in like manner experience a mitigated form of measles and scarlet fever. But since we have not yet learned the secret of attenuating at will the virus of these diseases, we should do the next best thing—by permitting the natural spread of their exciting poisons, *already* attenuated by a long course of cultivation in the same race and locality, as they now exist among us, we should protect our population against their pandemic and malignant diffusion.

is fully turned upon its apex, and the next epidemic is attended with disaster.

In this connection the change in the severity of scarlet fever as observed in England is worthy of note. Sydenham regarded it as a benign disease—a circumstance not surprising when we recollect how severely the English had recently been tried by selection through the plague. During the earlier half of the present century Dr. Gregory (Copland) estimated its mortality in England at about six per cent. of the cases. But during the past thirty years the severity of the disease is said to have been considerably increased. English physicians (*e.g.*, Barrow, *Brit. Med. Journ.*, p. 256, Aug. 13, 1881) dimly recognize this fact, without intelligent comprehension of its cause. According to the doctrines of the sanitarians, a better result should follow the great sanitary efforts which have been put forth in that country during the past forty years. The time has come, in fact, when it is a matter for serious inquiry whether the anxious endeavors of the English to "stamp out" scarlet fever are not to be reckoned among the causes of its increasing aggravation.

"Naturam expellas furca, tamen usque recurret."

From the evidence, of which these few specimens have been thus briefly presented, we may learn that certain ordinarily benign diseases can very easily be made to assume great malignity. Frequent exposure, and the hereditary tolerance acquired by natural selection, constitute important safeguards against such malignity. Isolation and the consequent unimpeded operation of the tendency to revert toward original types of existence, reduce and finally destroy all the security acquired by ancestral experience, leaving the victim of isolation in danger of disaster at any moment when a relaxation of vigilance may permit unwitting exposure to the causes of disease. We become capable of resisting heat and cold by frequent exposure to those conditions, and thus we acquire health—a possession which is cheaply earned at the expense of a sunburned face, or even a frosted ear. The way to become tolerant of diseases whose causes we cannot yet remove is through exposure to their action. Consequently, the proper course for the active sanitarian lies not in the attempt to combat all spreading diseases by the same narrow method. He should study the processes of nature, and should seek to enlist their aid in his behalf. He will then find that each disease requires its own peculiar management, and that this should vary in different localities and at different times. We do not eradicate malaria by dosing the fever patient with quinine, but by effectual drainage of the soil. In like manner cholera is not suppressed in India or in Ceylon by sanitary inspection or by household quarantine, but it disappears in the presence of irrigation and an abundance of food (*Nature*, p. 511, October 11, 1877).

Typhoid fever and typhus are seldom arrested by isolation and by hospitalization of the sick, but they soon cease under the influence of good diet, pure water, and fresh air. Small-pox could not be restrained by the most stringent quarantines, but as soon as we had learned how to attenuate its virus and to experience the disease in a mitigated form, it was deprived of all its terrors. Just so with the kindred diseases, scarlet fever and measles. They cannot be eradicated from their natural habitat by disinfection and isolation. If we ever learn the secret of their origin, we may possibly learn the art of preventing their generation. Or, if we should ever acquire the secret of properly attenuating the virus of these diseases, we would then occupy the same relation toward them which we now hold regarding small-pox. Till then the safest course is to allow their widest natural prevalence. If we endeavor to secure artificial protection by isolation, etc., we shall inevitably sacrifice the vantage-ground of heredity which we now possess, soon reaching something like the Japanese type of constitution, and rendering ourselves liable to similar disasters. If any given community occupies a position of complete seclusion, like that of the Pitcairn Islanders, stringent quarantine is a very proper measure for their adoption; but if we dwell in the world of living men, it is much better to fit ourselves for a fearless existence in that world. It is far better that one should fall here and another there in the passage through the training-time of youth, rather than that all should be compelled to go timorously through life, dreading an encounter with measles, or scarlet fever, or whooping-cough, at an age when least able to sacrifice the time or to incur the danger of such an experience. The proper work of sanitary administration, in countries where such diseases are endemic, should consist, not in the endeavor to make people believe that the natural subsidence of a periodical epidemic is due to official vigilance, or that its natural evolution is caused by the doctors "who don't report their cases," but rather in the effort to relieve the sufferings of those who are unable to help themselves. Provide hospitals for the victims of small-pox and scarlet fever if you will, and use them for the *relief* of people who cannot be properly cared for at home; but do not defeat the object for which they should exist by making them a terror to the community, as we have done in Chicago.

That our practical sanitarians have failed to reach these scientific conclusions is owing to the fact that, instead of studying the natural history of virulent diseases, so as to adapt their means toward the production of the largest benefit to mankind, they have simply adopted as their guides to action the uninstructed instincts of individual selfishness. They have forgotten that individual profit is often incompatible with the general welfare—that present luxury too often means future misery. Every one shrinks from death; but, under present conditions, it is better for the race and for the world that all in turn should die. In like manner it seems hard to suffer with measles and scarlet fever; but, in a country where they are endemic, and where there is every reason to believe that they continually originate, it is a worse thing for the community to become artificially filled with people who are liable at any hour to be prostrated by these diseases. The present behavior of our sanitary officials in this matter is no more worthy of respect than an attempt to abolish death without first discovering the secret of immortality. As the wise man makes no effort to live on earth forever, but only seeks, by obeying the laws of nature, to postpone the appointed day, so, by submission to the processes through which nature renders the body tolerant of contagion, we shall accomplish far better results for mankind than can ever be effected by "the hunting and extermination of various species of hypothetical pathological bacteria, even though it were actually possible to catch and exterminate legions." This manly utterance by Dr. Beale expresses the truly scientific opinion which we should everywhere maintain in opposition to the miserable sentimentalism about "domestic pestilences" with which our unscientific sanitarians are laboring to indoctrinate an unsuspecting public.

## CLINICAL STUDIES OF INEBRIETY.

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.

The following cases are presented as illustrating other causes prominent in producing inebriety, and which may properly be termed conditions of exhaustion. Like the gathering of many little rivulets at one point into a stream, these cases indicate the juncture of a long train of events and conditions combining from some special cause into inebriety. Back of this there is always a weakness or defect of nerve-element, an absence of reserve power to adapt itself to the varied conditions of the organism or surroundings, which may be either inherited or acquired. This, in most cases, will appear from a careful study into the history and character of the patient; also, the development of inebriety may be predicted with much certainty in the future from a knowledge of the defective organism. These cases dated from profound commotion of the nerve-centres, where evidently conditions of exhaustion were present, which were still further increased and intensified by alcohol. In my opinion, inebriety dating from some exhaustive demand on the functional or organic activities of the body in persons who have previously suffered from nutritive excesses, or have even been moderate drinkers, passes rapidly into chronic stages, from which it is difficult to cure. The practical inference is, no form of alcohol should be given medicinally in such cases.

Case I.—*Inebriety from Shock, from Loss of Fortune, and Nerve Depression, etc.*—B——, family history obscure, was early put out to work in the country, and suffered from hardships and poverty. At twenty he came to the city as a clerk, with an intense ambition to be rich. Twenty-five years of close economy, strictly temperate living, and hard work brought with it a fortune; but with it was developed a narrow, selfish egotism and a grasping ambition to acquire more money. With limited culture, and general suspicion of every one, and no faith in humanity, his life was a perpetual struggle on the lowest plane of activity. A large family shared with him this same spirit, and beyond the church and an occasional ostentatious display of equipage at some watering-place for a few days, they lived a quiet, secluded life. At fifty he was a hale, hearty, temperate man, full of activity, and working regularly every day. He was regular in all his habits, rarely using any stimulants except wine, then never at home, but only when urged by some friend. By a sudden combination of events he became bankrupt, and when he realized the situation he purchased a case of brandy, and went home. For two weeks he remained in bed, drinking all the time, refusing to see any one, but giving some general directions to his son. Then he recovered and went out, displaying unusual energy and skill. A week later he came home intoxicated, and could give no reason, but seemed to regret the cost more than any other thing. From this time he became intoxicated two or three times a week, coming home after dark, and complaining bitterly of the expense. After a year he resumed business, and was prosperous; it was noticed that he drank less often as his fortune improved, and was seldom intoxicated.

Symptoms of failure of the nervous system, marked by trembling, sleeplessness, and inability to concentrate his mind on any subject more than a moment at a time. For this a consulting physician ordered rich diet with wines and whiskey. He drank harder than ever, and was intoxicated every week, became suspicious of his family, lost all sense of truth and honesty in his business, gave worthless checks, disguised his signature, then denied it, and caused infinite trouble and annoyance to his firm. All his previous habits of life changed, and at last his business was taken away from him by his sons, and he manifested the most extraordinary duplicity of thought and action. During the next two years all his energies were concentrated to procure spirits by every species of fraudulent device and strategy. Then he came under my care, with all the usual delusions of persecution and capacity to stop drinking. He was very much broken down in mind, and required incessant watching, was irritable and suspicious, and had no other thought but alcohol and how to procure it. After two months' residence in the institution, he suffered from dreams of drink, which came on like a paroxysm, during which he would walk about, staggering, and talking like a drunken man, then fall asleep for many hours, and awake confident that some one had been giving him spirits. These attacks came on once or twice a week, and he wrote home that the officers of the asylum gave him spirits for the purpose of keeping him. His son came on to visit him, and during the night, after another dream, paroxysm took place, in which every symptom of complete intoxication was present. In the morning the father asserted that he had been given spirits, but just how was not clear to him, and the son believed him, and the result was that he went home. These paroxysms disappeared when he could procure spirits. Soon afterward he found opium a substitute for alcohol, and died within a year from an overdose. The family still believe that he procured spirits or had them given him at the institution for the purpose of keeping him. The shock to the nerve-centres from loss of fortune and profound depression following, developed inebriety at once, simply because nature demanded relief, and found in alcohol a temporary sedative. The withdrawal of spirits at the institution, was followed after a time by paroxysmal dreams of drinking, a not uncommon event in chronic cases, especially after the first two weeks of treatment. In this case they were unusual both in the time of appearance and severity of attack. What special determining causes brought on inebriety cannot be known at present, but I am assured that future studies will reveal these, and all the conditions which enter into this disease.

Case II.—*Inebriety from Shock of Fear—Recovery—Relapse.*—B——, a merchant, with a marked family history of consumption and rheumatism, was a strictly temperate man at thirty-five, in good health, with regular habits, pleasant social relations, and prospering in business. From childhood he had manifested an intense fear of lightning and thunder, being obliged to go to bed prostrated during a long-continued storm. When he grew up this fear increased into a short paroxysm of fever when a severe storm came up, sometimes lasting a day or more after. While returing from New York the express train jumped the track, and ran along over the ties at high speed for some minutes. It was in the edge of the evening, and the lamps were shivered and the window-lights broken. The noise and suspense, with the jolting of the car, caused an intense fear and agony of mind for several minutes. When the car stopped he was found to have lost all power

of motion, and had to be lifted out and carried to a hotel near by. He could not speak, was very pale, and seemed in a fainting fit. At the hotel he was given large quantities of alcohol, and recovered his power of speech. The third day he was carried home suffering from intense exhaustion, and was unable to rise from bed for many weeks. His appetite failed him, and he was unable to sleep. Tonics and stimulants were freely given. At night a slight fever, with delirium, came on, which lasted ten days or more before it was broken up. He recovered slowly, but continued the use of alcohol regularly. The next year he drank more, and began to neglect his business, spending most of the time at a hotel, boasting what he could do. He complained of undefinable pains and aches, which he called malarious, and used alcohol to relieve them, being intoxicated from one to four times every month. Symptoms of persecution appeared; he was intensely egotistical and impulsive. He never seemed to realize that he was drinking to excess, and had no clear convictions of his case or danger. Rheumatism and dyspepsia followed each other alternately; sometimes one would be prominent, then the other. At one time he would be deeply religious, then be indifferent about all religious matters. He would be seized with attacks of extreme restlessness and agitation, in which he would appear childish and feeble. He was brought to the asylum, and remained three months, going away improved. He remained at home for the year following, doing little, and was seemingly in good health, then, from some unknown cause, he relapsed, and is now a chronic case. The direct cause here was the profound excitement from the fear of accident on the railroad, followed by functional paralysis, ending in inebriety, excited by the use of alcohol. He evidently had a nervous organization that was defective, manifest in the morbid fear of lightning and the prostration which followed. The persistent use of alcohol as a stimulant after any powerful shock to the nervous system is attended with more or less danger of inebriety.

Case III.—*Inebriety from the Excitement and Exhaustion incident on Change of Life and Vocation.*—H——, father died from some obscure brain trouble, grandmother on mother's side died insane. Became a machinist, and at forty-one years of age was part owner of a large mill, and living a very regular temperate life. He was not an abstainer, but used wine and beer occasionally without any taste for it. He made an invention at this time which brought him an immense income, and was elected by accident to Congress. His quiet retiring manners and reputed wealth drew about him a large circle of obsequious flatterers. He moved into an elegant house, and gathered about him luxuries, and lived a life of excitement and change. After his election the second time he began to keep late hours, give suppers with wine, and keep fast society. He neglected ordinary exercise, and was ambitious for political preferment, then he began to use brandy, and a year later he was frequently intoxicated, growing worse rapidly, until he was seized with an epileptic convulsion; was put under the care of a physician in a private hospital. Soon after his fortune vanished and his friends also, and he went to work again in the same mill. He continued to use spirits and two years after was brought to my care. He was very much prostrated physically, and his mind greatly disturbed with delusions of fear and trouble ahead of him. He was extremely irritable and wanted to get away, and manifested much cunning in efforts to procure spirits. His improvement was slow, but after five months' treatment he went home, and soon after relapsed. He went to Boston under Dr. Day for two months, coming back much better. He is now at work, occasionally using alcohol to excess, and at times manifesting the most lively fear of using stimulants again, attending meetings, and urging others to sign the pledge.

Here was a long preliminary stage of occasional drinking, up to the time of sudden elevation to wealth and prominence. The marked change of circumstances and living, with the excesses which followed, particularly of the nutrient organs, want of exercise, and proper sleep, were the very conditions from which inebriety would be naturally developed. Other diseases would have followed these changes if inebriety had not appeared. I have noted cases of this kind where inebriety burst out with much intensity, then died away, or was followed by Bright's disease, or acute rheumatism; while these diseases were active the desire for alcohol diminished, the patient either taking nothing or a small quantity at long intervals. Sudden elevation to wealth, or total change of living and circumstances at or after middle life, is followed by a certain strain of the nervous system to accommodate itself to the new conditions. If at this time there is any defect of the nervous system, either inherited or acquired, the exhaustion will be greater and the door open for many diseases. In the excitement incident to any great changes of living alcohol will always be found the most available means of relief, hence inebriety will be encouraged from the start.

Case IV.—*Inebriety, from Grief and General Mental Depression—Recovery—Relapse and Death.*—X——, a lawyer in large practice and occupying a very prominent position, lost his only son from an accident, and soon after began to use alcohol to excess. Within six months from the time of the first use of alcohol he was taken to the insane asylum, and was discharged as cured in six weeks. Returning, he began to use alcohol again, and finally went to the South, traveling to different health resorts, getting no benefit, but drinking harder than ever. I was consulted and found the following history: His parents died, when he was a child, of consumption; one brother is insane, from exposure and injury in the army, the other is a nervous invalid, broken down in mind and body. This patient while a young man was extremely fond of the pleasures of the table, and smoked very freely for many years, then gave it up and seemed to be reformed and very temperate. At thirty-one years he joined the temperance ranks and was an ultra prohibitionist, but he lived on the richest food and was impulsive in his tastes. He was generally neglectful of ordinary sanitary rules, such as regularity in eating and sleeping. At forty-four his son was killed by an accident, and the effect on his mind was so intense that he went to bed for twenty-four hours and seemed in a kind of stupor, then roused himself and called for brandy, drinking freely; resumed his business, using stimulants freely many times a day. Within a week he was intoxicated, and from this time was nearly always under the influence of alcohol. I advised a certain course of tonics, residence in the country, perfect quiet, and absolute withdrawal from alcohol, under the care of physicians. This failed after a few weeks, and he went under Dr. Mason's care, at Fort Hamilton. Six months of treatment ended in recovery, and resumption of business as before. Two years after, he relapsed after a protracted pe-

riod of severe labor, and gave up everything—drinking for two weeks severely; then signed the pledge and began to lecture on temperance; later he relapsed and died of acute pneumonia within a year. The shock from grief overwhelming the nerve centres developed inebriety, because there was already a nervous diathesis and predisposition, which was exhibited during early manhood in nutrient excesses. I append notes of five cases, as illustrating more fully these obscure causatious cases, whose general history differs but little from those described after the onset of inebriety.

Case V.—Born of insane and epileptic parents. Was eccentric and fanatical. Built up a fortune, and was a man of great force of character, and intensely egotistical. Was a gross eater, but was almost insanely opposed to alcohol in any form. When fifty-six years of age was thrown from his carriage and made unconscious for a short time, but apparently sustained no marked injury. Suddenly he began to use alcohol, and was a confirmed inebriate for the next six months, up to death, which followed from some obscure heart disease.

Case VI.—Inherited a marked neurotic tendency; was exceedingly temperate up to the time of marriage at thirty-six years of age. A bookkeeper, intelligent and respected. Soon after marriage he became an inebriate, and is now a "repeater," going from one asylum to another, very much broken down in health and a confirmed case. Sexual excess at marriage was undoubtedly the exciting cause; he is always worse at home in the company of his wife. He would have impulsive cravings for spirits after a short visit from his wife at the asylum, and at no other time would this be noticed, confirming the theory of the exciting cause.

Case VII.—Son of a clergyman, with a marked history of consumption and rheumatism for generations back. At twenty-two, in college, from disappointment and loss of class honors, he drank to intoxication, and continued until expelled from college. He is now a hopeless incurable.

Case VIII.—A physician with an obscure family history, in good practice and prosperous. Suffered intense mortification from a suit for malpractice which was decided against him. Moved away discouraged, and began to drink spirits, becoming an inebriate very soon. Was egotistical, full of delusions, and is now an inmate of the State prison, for forgery committed while intoxicated.

Case IX.—A strong, hearty workman on a farm, with no family history of nerve disorder, began to use alcohol to intoxication after an attack of colic from indigestion and over-work. He had used ice-water freely during the harvest season past, and had eaten to excess. He became a paroxysmal inebriate, having distinct periods of sobriety, followed by long seasons of excess. He has been twice under treatment at different institutions, and relapsed each time. Before the attack of colic he had not used any form of spirits.

Case X.—A lawyer, with a history of insanity and inebriety back in several members of the family; was temperate and healthy up to forty-two years of age. At the close of the election campaign of 1873, in which he had participated, his joy was so great that he drank wine to intoxication at a private dinner given by the successful candidate; from this time he went down rapidly, drinking every week, and was soon a chronic case.

These cases are sufficient to indicate the necessity of taking wider views of the obscure causes which are at work in producing inebriety. They also point out some of the degenerate conditions of nerve force and energy which are at the foundation of all inebriety. The practitioner should ever bear in mind the fact that exhaustion of the nerve-centres is a condition which can only be understood from close observation and study of the case, with a thorough acquaintance of all surroundings and natural history of the patient; that physical exhaustion and overwork, particularly excesses of any kind, opens the door and invites disease, of which inebriety may be the most natural sequence.

## WEAK SPOTS IN OUR KNOWLEDGE OF MATERIA MEDICA.*

By H. G. PIFFARD, M.D.,
NEW YORK.

Gentlemen: It is a self-evident proposition that the carpenter should be familiar with his tools if good work is to be expected at his hands. So we, as physicians, should be familiar with ours, and there are none more frequently employed by us than drugs. It is for the study of these that we are associated, in the hope that by earnestly devoting ourselves to their investigation we may be enabled the better to understand their modes of action and several capabilities, to the end that disease may be the more safely, quickly, and pleasantly removed.

It may not be inappropriate, then, to consider some of the special lines of study that may profitably engage our attention in connection with the general subject that unites us.

Naturally, the first points that strike us in connection with any drug that we may encounter are the qualities or properties that it possesses, as revealed to us through the medium of our senses, unaided by chemical or microscopical manipulation—in other words, its ordinary physical properties. Here sight, taste, touch, and smell each play their part in enabling us to identify the different bodies, and, what is of equal importance, to form in many instances an opinion as to the quality of the substance under consideration, to judge in a measure whether it has been injured by adulteration, has become deteriorated through age or improper methods of preservation, or has been impaired by unsuitable pharmaceutical manipulation.

The cultivation of our special senses, so as to enable us the better to identify and to judge of the qualities of drugs may, I think, profitably engage a portion of our time. Chemistry and the microscope will carry us still deeper in this direction, and are, of course, not to be overlooked.

In possession of a drug, we are next led to inquire as to its action. In what way does it affect the human system; what phenomena will follow its introduction into the body; what disturbances of function or structure will it cause; how soon will these become evident; in what order will they arise; and when will they terminate and the normal condition of the body be resumed? These questions require answers. Let us, for example, examine the action of one of the more familiar articles of the materia medica, namely, *sulphate of magnesia*. If given in full doses to a person in health, and accustomed to daily rectal evacuation, it will, within the first twenty-four hours, greatly increase the number of evacuations, but following this there will be a period during which the number of evacua-

* Abstract of an address delivered at the first meeting of the New York Materia Medica Society.

tions will be fewer than normal. In other words, we shall have an artificial diarrhœa, followed by an artificial constipation. These phenomena—the diarrhœa and the constipation—are both the effects, or rather the consequences, of the drug, for neither would have occurred had the drug not been given; but what strikes us particularly, is the fact that quite opposite conditions have been induced, the one following the other. To these opposite conditions, the terms primary and secondary action, early and remote effects, or action and reaction, have been given. The terms most commonly employed are the ones first given above, and we are reasonably familiar with these actions in connection with a limited number of drugs, chiefly those which are usually given in a single large dose. The secondary action or remote effects of those drugs that are given in repeated doses, however, well merit further investigation.

Looking further, we encounter the dogmatic statement of Sydenham: "*Opium sedat;*" to which Brown vehemently replied, "*Meherele opium non sedat, opium excitat.*" These propositions, so diametrically opposed, are yet both true, as universal experience attests. Either of these contrary effects may be obtained almost at will; it is simply a question of dose. With a small dose, say five or ten milligrammes of opium, we may expect excitement, while with a larger one of fifty or a hundred milligrammes we shall have sedation. This apparently opposite action of large and small doses is familiar to us now in quite a number of drugs, but how extensively these phenomena prevail is a matter that merits, and I think will fully repay, further study.

Another question worthy of examination is the modifying effect of chemical combination on active drugs. Do we get a true hybrid effect, or does the action of one or the other component parts appear to prevail in a given instance? If we take the salts of morphia, of quinia, of pilocarpin, or of mercury, we can promptly reply that the base preserves its own characteristic action, apparently little modified by the acid that is combined with it. On the other hand, if we take the compounds of iodine or of bromine, we find that the bases are the least important factors, the first-named bodies seeming to preserve their identity in great measure throughout the entire line of saline combinations. Which drugs we have in combination, like morphia, etc., which like iodine and bromine, and which again, if there be any such, that exhibit a true and equal hybridity of effect, if such an expression may be allowed, are questions that await settlement.

The effects of the mixture of two or more drugs is likewise of interest and of importance, more especially in a therapeutic relation. Under what circumstances will the components of a mixture aid each other in accomplishing the end sought—the restoration of health; and under what circumstances will they conflict and result in a mixture that may be almost therapeutically inert? We all know, as a matter of experience, that there are phases and conditions of syphilis in which a mixture of mercury and the iodide of potassium will prove more efficient than either given alone; and we know, equally well, that there are other phases of this disease in which one or the other of these drugs proves more useful than their mixture. Let us, then, seek to determine the effects of mixture as regards other drugs and other diseases.

Still another interesting field invites exploration, to wit: The specific relationship of particular drugs to particular organs of the body. Thus we all recognize the fact that mercury and pilocarpus exert a special influence on the salivary glands; that arsenic and pilocarpus exert a special influence upon the skin; that cantharides affects the urinary tract; and that belladonna affects the eye. Let us extend our inquiries in this direction, to the end that we may obtain a more precise knowledge of the organic or local sphere of action of at least the more potent and important of the articles of the materia medica.

The relationship of drug-action to acute pathological processes—for instance, as aconite to inflammatory congestion, quinia to inflammatory exudation—needs further study. Have we any drugs that exert direct effect on the acute fatty alterations of the liver that we meet with in yellow fever and in phosphorus-poisoning? Unfortunately we have not, at least so far as is known to me.

Again, the relationship of drug-action to chronic pathological processes invites us. We know something of the effects of mercury on syphilis, of iodine on struma, but have we any drug that will efficiently control that too prevalent condition or diathesis of suboxidation that doubtless lies at the root of so many gouty, rheumatic and other ills. Candidly, we must confess that such a drug is yet to be found, and if two thousand years have failed to reveal it to us by chance, our main hope for its discovery in the future must depend on earnest investigation.

The influence of drugs in the relief of particular symptoms, as pyrexia, pain, etc., should engage us. As regards the former of these, we know the effects of the cold douche, of the so-called apyretics, etc. As regards the latter, we know in a general way that opium is capable of controlling pain, wherever located, but that it does so by benumbing, as it were, the entire system. We also know that aconite and gelsemium are capable of relieving certain trifacial pains, but unfortunately we do not know of any drug that will specifically control the agonizing torture of a nephritic or biliary colic, without at the same time obtunding the general sensibility of the rest of the economy.

In these few lines, I have, as you will perceive, endeavored to indicate some of the weak spots in our knowledge of materia medica, and I will now close by expressing the hope and expectation that if each will earnestly work in some of the lines that are opened to us, it may not be many years before we shall be satisfied that our labor has not been entirely in vain.

---

TAKING ISSUE WITH A HEALTH BOARD.—The Board of Health for Brooklyn is prosecuting Dr. Paul H. Kretzschmar for an alleged violation of the sanitary code, which provides that "every physician shall report to the Sanitary Bureau, in writing, all cases of contagious diseases which he has prescribed for or attended." About a week ago a case of scarlet fever occurred among Dr. Kretzschmar's patients. He informed a member of the Board of Health personally of this, but he did not send a formal notification as required by the rules. Dr. Kretzschmar holds that the rule requiring that the notice should be sent on a postal card is not binding, and that it is likely to result in the spreading of contagious diseases. He believes that all contagious diseases should be reported personally to the members of the Board of Health. Many of the leading physicians of Brooklyn take this view, and Dr. Kretzschmar's case will be a test one. Dr. Kretzschmar is connected with the Long Island Hospital.

# Reports of Hospitals.

## NEW YORK HOSPITAL, N. Y.

## A CASE OF SECONDARY SYPHILIS.

A Clinical Lecture.

By W. H. DRAPER, M.D.,

ATTENDING PHYSICIAN.

I show you to-day, gentlemen, a case of secondary syphilis, which presents some points of interest.

The patient's age is twenty-four. He is a native of the United States, single, and a groom. In November he had a chancre, which appeared a week after connection. It was treated locally only, with bluestone. He was well until four or five weeks ago, seven weeks after appearance of chancre, when he began to suffer from frontal headache, lachrymation, and lassitude. After a complete intermission of a few days, the symptoms mentioned returned with greater intensity. The frontal headache lasted day and night, was very pronounced, and attended with lachrymation. His head was sore to pressure. Five weeks ago he experienced pain in the shoulder and partial disability of the arm. A week ago an eruption appeared upon the trunk and upper extremities. On admission, his respiration was 20, pulse 84, temperature 98.4°. Patient is well nourished, and has no œdema. The posterior cervical, epitrochlear, and inguinal glands are hard. On the forehead and neck there are reddish papules. There is slight desquamation. These papules are discreet, elevated, and surrounded by normal tissue. He has no alopecia. The U. S. solution of morphia was given, and the patient put under the usual treatment. Such is the history of the case.

A week after connection, this man noticed what he describes as a single sore upon the frænum. We distinguish between the unique infecting sore and the chancroid. The latter is apt to be multiple, and appears a short time after intercourse; the chancre is unique, and appears one to three weeks subsequent to impure contact.

This man has swellings, not only in the glands in the immediate neighborhood of the sore, but also in those more distant: in the posterior cervical chain, in the chain running down the arm, especially the epitrochlear, and in the glands behind the ear, near the mastoid process.

The unique sore occurring one to three weeks after connection, and the coincident adenitis, are signs of constitutional syphilis, just as much as the pustule of small-pox is a sign of small-pox.

Another point in which the history is classical, is the time at which the secondary symptoms occurred. We call this eruption a secondary manifestation, simply from its relation to the primary sore, as it is termed; but the chancre and the adenitis are as much signs of constitutional disease as the former. This eruption appeared seven weeks after the primary lesion. It occurred in the localities in which it is most likely to be seen, on the anterior aspect of the body and the inner aspect of the extremities. Often it is not observed, because it is most prominently developed on those parts covered by clothing. Where habits of cleanliness are not practised, it may escape detection. Too much stress should not be laid upon statements as to the absence of eruption in the early period. Though it may be extremely sparse, yet, in the majority of cases, it does occur. This man has a very general one, so manifest, and so like measles, that it might readily be mistaken for that disease. He has a copious eruption on the face, trunk, extremities, and hands, which is as extensive as that of rubeola; it presents a similar appearance, has a vivid color, and though it does not present a crescentic grouping, yet, to the superficial observer, it might be mistaken for the exanthema mentioned. What makes the mistake more easy, is the fact that we have much lachrymation in this case. If you pass your finger over the eruption, you can feel the papules.

The color is not so marked in the early as in the later stages, but, recollect, color is by no means a safe guide. In many cases of non-specific eruption, provided the patient is cachectic, you may get a brown stain suggestive of syphilis. This is especially true of erythematous eruptions on the arms and legs, where the circulation is feeble.

During this period, you may observe in the throat a development of mucous patches. These are more abundant the less copious the tegumentary eruption is. In this you see a striking analogy between syphilis and the exanthematous fevers, for in these, also, the lesions of the mucous membranes are more intense the milder the eruption upon the skin.

The next point to which I wish to direct your attention is the neuralgic element. This man began to suffer from pain along the distribution of the fifth nerve. This symptom preceded, as it generally does, the development of the eruption. With these pains, which may affect a single branch of a nerve, or invade more or less all of its rami, there is apt to be pain in the joints and bones, and great lassitude. They are the symptoms of fever. Such pains are often very severe, and commonly vary according to the degree of febrile action in intensity. They differ from those which occur later with periosteal inflammation, and tubercular inflammation of the skin; they are merely functional, and associated with the syphilitic fever.

This case illustrates very well the theory propounded by Hutchinson, that syphilis is an exanthematous fever analogous to small-pox, scarlatina, and measles. It has a period of incubation, a period of eruption, and sequelæ. These are certainly distinctly made out in many cases of syphilis. The period of eruption, corresponding to that of the exanthematous diseases, is clear in this instance. The analogy does not hold good when we come to compare the length of time during which the stages of incubation and eruption last, but so far as the stages themselves are concerned, it is striking. The period of incubation, between connection and the appearance of the eruption, is generally six to eight weeks. The period of the syphilitic exanthema is extremely irregular. The eruption may last from three to six weeks, but unfortunately it has a tendency to recur, and may thus extend over a year or eighteen months, with frequent repetitions upon the skin and mucous membranes. Then, at any time during the first year, we may observe the consequences manifested by destruction of tissue, the development of gummy tumors, periosteal inflammation, and tubercular inflammation of the skin. These are the sequelæ analogous to those which follow, in a much shorter period, from the exanthematous fevers. This hypothesis in regard to syphilis is perhaps not practically useful, but if you carry it out, you can see how strikingly syphilis corresponds to some of the eruptive fevers.

The ordinary eruptive fevers vary in severity in

different patients, and different persons have varying susceptibility to their influence. Some acquire small-pox, scarlet fever, or measles upon the least exposure, while others are not affected. Some have very mild, others very severe attacks. With the majority of patients, measles, small-pox, and scarlet fever are comparatively mild diseases, producing no serious harm, but in others these exanthemata may produce disastrous results. The same, in respect to promiscuous sexual intercourse, is true of syphilis. I have seen men who have led the most reckless lives, and yet have never contracted syphilis. Many have the primary sore and the early eruption, and are no worse after these than they would be after measles. Many, on the other hand, are so susceptible to the poison of this disease, that they pass through all its stages, and become the victims of its most profound lesions within a period of eighteen months.

These facts in regard to the varying degree of severity of syphilis, it is important to bear in mind. Many cases of syphilis, supposed to be cured by vigorous treatment—mercury in the early stages, and mercury and the iodide of potassium in the later—would probably have got well without any treatment at all. The truth is that these two remedies unquestionably have a great control over syphilitic lesions as they manifest themselves. That they eradicate the disease is something which I do not think can be predicated of them. We can control the malady, we can diminish the tendency to a recurrence of the lesion, we can keep the patient tolerably free from annoyance during the secondary stage, but, having done this, we cannot say that we have protected him against the more serious consequences. When these more serious consequences appear, however, we can control them by the iodide of potassium, or by this remedy in combination with mercury. There is nothing in the whole range of therapeutics which exhibits such certain and such satisfactory results as the so-called specific treatment of syphilitic lesions. At the same time, we are not justified in assuming that this specific treatment will eradicate the *frus et origo mali*. It will control and cure the lesions, but it cannot insure against the possibility of recurrence.

You have seen in this patient a good illustration of the evolution of the malady in the first stages. It is quite a classical case.

Can the severity of the disease be prognosticated from the appearance of the eruption? It is said by good authority, that when there is a copious erythema within three months after the sore, the prognosis is better than when the eruption is sparse and papular, rather than erythematous. In this instance we have a good illustration of what is known as a syphilitic erythema, though it is to a slight extent papular. So far as the eruption is concerned, we might say that the chances of his not having serious sequelæ within a year are very good. This is a dangerous sort of a prognosis to make, but still, cases like this, where there is but little papular element, are considered favorable.

It might be asked whether the occurrence of so much pain as he has suffered would not render the prognosis more serious. I think not. I regard the occurrence of neuralgia in syphilitic fever as purely accidental. If this patient were suffering from small-pox or scarlet fever, pain would probably be a more prominent symptom than it is commonly in those diseases.

This man has been put upon the biniodide of mercury. There is considerable difference of opinion as to the best method of treatment of syphilis in its early stages, that is to say, in regard to the best preparation of mercury; about the drug itself, there is no question. The late Dr. Bumstead preferred blue pill. He gave gr. iij. t. i. d. until slight salivation was produced. The protiodide has been a favorite in this country, because it was a favorite of Ricord's. The bichloride has been administered by the mouth, and hypodermically. In the latter way it produces its effects very promptly. I have not had much experience in this method, but Dr. R. W. Taylor, who gives gr. $\frac{1}{12}$ to $\frac{1}{8}$, once a day, finds that a marked effect is produced upon the fever and the eruption in a few days. This patient has been put upon the biniodide, which is rather more marked in its effects than the bichloride. Another very good method is to give small doses of calomel, gr. $\frac{1}{15}$, every hour. This will sometimes produce salivation within twenty-four hours. As soon as ptyalism is produced, the good effects of the drug are manifested in the relief of the symptoms. After salivation has been effected, caution is necessary. The remedy should be exhibited in doses sufficient to keep up merely a moderate ptyalism. We were also giving this man opium, to relieve his pain.

This patient's primary lesion healed in the course of fourteen days, under bluestone treatment. This is the case in most infectious sores.

The distinction between the unique chancre and the multiple non-infecting sore, is one upon which you can generally rely, though not absolutely. I have seen sores which were supposed to be chancroids turn out to be chancres. I have a suspicion of all sores appearing in one to three weeks after connection; whether they be single or multiple, soft or hard, I think they are infectious. Sores appearing immediately after connection are chancroids. Hardness, like the swelling of the glands, is a symptom of infection.

Cure for Hydrophobia.—An editorial writer in the *N. Y. Times* discourses facetiously regarding the following method of "curing" hydrophobia: "Dr. V. Galtier, a veterinary surgeon, of Lyons, France, has lately made a most remarkable and valuable discovery in regard to rabies. It is well known that the virus by which rabies is communicated from one animal to another, and which produces hydrophobia in the human subject, is contained in the saliva of rabid animals. Hitherto it has been supposed that in order to communicate disease this virus must enter into the circulation, but Dr. Galtier has found that this is a mistake. The virus acts by being brought in contact with the nerves, and when introduced into the circulation it acts as a preventive of the disease. Astonishing as this assertion may seem, there is, apparently, no room for doubting it. Dr. Galtier injected the saliva of a mad dog into the veins of ten sheep, and at the same time placed the saliva of the same dog in contact with the nerves of ten other sheep. The latter all died with every symptom of rabies, while the other ten remained perfectly well. He also ascertained that when the virus of rabies was injected into the veins of sheep, it was impossible to produce rabies in them by any subsequent experiments. He has thus discovered that hydrophobia is purely a disease of the nerves, and that to inject the virus of rabies into the circulation is a certain protection against the disease, at least in the case of sheep."

# Progress of Medical Science.

CHANGES IN THE SPINAL CORD IN INFANTILE SPINAL PARALYSIS AND IN PROGRESSIVE MUSCULAR ATROPHY.—Drs. Roger and Damaschino conclude a very elaborate paper upon the lesions of the spinal cord in infantile spinal paralysis and progressive muscular atrophy. The authors conclude with the following résumé: 1st, the characteristic change in infantile paralysis is a lesion of the spinal cord, resulting in atrophy of the nerves and muscles; 2d, the lesion is situated more particularly in the anterior portion of the gray substance of the spinal cord, where it evidences itself by foci of softening; 3d, this softening is of an inflammatory nature, and the disease is a true myelitis; 4th, infantile paralysis should accordingly be named spinal paralysis of infancy, and is to be nosologically classed among affections of the spinal cord as a myelitis; 5th, as for progressive muscular atrophy, this is to be differentiated from infantile paralysis as well by its symptoms as by its anatomical lesions. The change in the cord consists essentially in an atrophy of the motor cells, without any foci of inflammation. — *Revue de Médecine*, February, 1881.

VISCERAL SYPHILIS—SPECIFIC NEPHRITIS.—M. Barthélemy at first quotes from the London Clinical Society. At a meeting of this body, held in January, several cases of hereditary syphilis were reported, in which, among other affected organs, the kidneys had been involved, being the seat of parenchymatous nephritis. Referring to such patients, Dr. Hutchinson stated that when death occurred as a consequence of syphilis, the fatal result was directly due to the nephritis. Dr. Coupland was convinced that patients who had been suffering for a long time from syphilis acquired a true predisposition for parenchymatous nephritis, and were liable to death from this condition. As a result of his personal researches, M. Barthélemy offers the following: Nephritic lesions are among the complications of all the stages of syphilis, even of the acquired disease. Such nephritic complications are always grave. Nevertheless, they are sometimes curable, not only when they occur in adults as a result of acquired syphilis, but also in children affected with the hereditary disease. Together with other specific lesions, they have this characteristic in common: their gravity is in proportion to the age of the patient's syphilis, and the period of time which has elapsed before specific treatment was begun. In children affected with hereditary syphilis, specific nephritis should always be taken into consideration, when the patients are subjected to accidents for which nephritis may be held accountable. When a physician meets with nephritis in an adult, he would do well to think of the possible specific origin of the renal difficulty, in view of the great number of cases of unsuspected syphilis.—*Annales de Dermatologie et de Syphilographie*, April, 1881.

CHOLECYSTOTOMY IN A CASE OF DROPSY OF THE GALL-BLADDER.—Dr. Lawson Tait reports this case: The patient was a woman, forty years of age. Different diagnoses had been made, such as cyst of a floating kidney, tumor of the head of the pancreas, and dropsy of the gall-bladder. Finally the opening of the abdomen was decided upon. In the median line an incision was made, extending two inches above and the same distance below the umbilicus. The aspirator needle being introduced into the summit of the tumor, from twelve to fifteen ounces of a whitish fluid escaped. The gall-bladder was then opened. On inserting the finger into it, the pressure of a freely movable calculus was ascertained, and on further examination, another rather larger one, pyriform in shape, was found obstructing the cystic duct. It was deeply imbedded in the walls of the latter, and was undoubtedly the cause of the dropsy. This calculus was extracted with great difficulty, on account of the extreme mobility of the gall-bladder, and the intimate adherence of the foreign body to its walls. Lithotrity was practised with great care. The nucleus of the calculus was crushed by means of a pair of pincers. The cavity of the gall-bladder was then washed out in such a manner that not a fragment of the stone remained. Finally, the incision in the gall-bladder was united by suture to the upper extremity of the abdominal wound, leaving a free opening communicating with the viscus mentioned. The rest of the abdominal incision was closed in the usual way. The wound in the abdomen was washed with antiseptic solutions. Nothing noteworthy occurred. Bile flowed normally, until September 3d, sixteen days after the operation, when washing with the solution was replaced by the application of zinc ointment. By September 9th the wound had cicatrized, and on the 20th the patient returned to her home, having gained thirteen pounds during her stay in the hospital. In a case of this kind, Dr. Tait advises that an explorative incision be made early, in order that the nature of the disease may be ascertained, and the necessary operation performed. Antiseptic precautions should also be employed.—*Archives Générales de Médecine*, June, 1881; *Medico-Chirurgical Transactions*, vol. xlv., 2d series.

ABSENCE OF THE LEFT KIDNEY.—At the post-mortem examination of the body of a patient, twenty-two years of age, who had died of interstitial nephritis after repeated attacks of uræmic eclampsia, the left kidney, as well as the left renal artery, were found to be absent. The aorta in this situation gave off but one branch. After careful removal of the bladder, only one ureter could be seen opening into it, which belonged to the right kidney. The orifice of the left ureter was sought for in vain. The right kidney occupied its normal position and had the ordinary dimensions of a healthy organ. It was hard to the touch, and, on removal of the capsule, presented a slightly granular surface. On section the pyramids were seen to occupy their normal situation, and to be directed toward a single calyx and pelvis. There was no association or fusion of two kidneys to form a single one. The greater part of the pyramids were altered. Only three had retained their normal dimensions, the others were visibly diminished in size or had almost entirely disappeared.—*Archives Générales de Médecine*, July, 1881.

ON TENDON REFLEX IN THE DIAGNOSIS OF DISEASES OF THE SPINAL CORD.—Dr. J. Hughlings Jackson reviews Buzzard's paper on this subject in the July number of *Brain*. It is a contribution to the arguments which the clinical facts afford in favor of the reflex mechanism of the phenomena. Buzzard points out that a convenient mode of testing the patella reflex is by lightly touching the patient's thigh with the left hand, whilst with the right a blow is given with a percussion stethoscope or hammer on the ligamentum patellæ, the patient being

seated with his foot resting firmly upon the ground and slightly advanced. The quadriceps is felt to contract. The mode is especially convenient for the examination of females.

By a rough diagram, Buzzard shows the nervous arc of communication extending from the tendon to the posterior roots, anterior bone, anterior roots, and thus to the muscle. He remarks that the integrity of the arc insures the contraction of the muscle (if *it* be healthy) to a blow on the tendon. On the other hand, the response to a blow nearly always proves that the arc is not seriously interrupted; but he makes the important observation that there is an exception to this rule. There may be atrophy of some ganglion cells in the anterior bone. If this lesion existed alone, tendon reflex (as shown by another diagram) would be abolished; but if the lateral column be sclerosed, the inhibitory influence from above is so much interrupted that reflex occurs. In cases, therefore, of lateral sclerosis we may get the patella tendon reflex preserved, although the nervous arc is not intact. He ascribes the exaggeration of tendon reflex to the interception of controlling influence which comes down through the lateral column, and points out that the absence of this influence (*e.g.*, in a case of hysterical paralysis) produces similar effects to its mechanical interruption by means of sclerosis, though in the former case they are only temporary. He points out that in spastic paraplegia, secondary to myelitis, the exaggeration of reflex may be connected with a temporary interruption (something short of sclerosis) in the lateral column, and may disappear as the lesion clears up.

Buzzard has in several cases witnessed the occurrence of ankle-clonus in hysteria, which in one case ceased suddenly, so to speak, on the patient's recovery. He points out, therefore, that the occurrence of ankle-clonus must not be regarded as conclusive evidence of a structural lesion of the spinal cord. He describes an extremely interesting case of a man in whom the patella tendon reflex was absent on each side during an attack of syphilitic myelitis, which apparently affected a lateral half of the cord. In the limb corresponding to the seat of lesion—the left—it was absent in connection with motor paralysis and muscular wasting, the facts apparently pointing to the arc being "cut" in the anterior bone. In the right limb it was also absent, but in entirely different circumstances, for here the motive power was perfect and the muscle not wasted, but the cutaneous sensibility was lost. To cause this affection of sensibility, the sensory part of this arc must have been cut. This showed that the lesion, although largely confined to the left half of the cord, encroached a little upon the posterior gray matter of the right half also. In confirmation of this view, Buzzard points to the fact that there was a patch of cutaneous anæsthesia in the neighborhood of the left trochanter. Buzzard makes the important suggestion, that the patella tendon reflex is lost somewhat easily, and that it will often be found wanting when there is but a slight lowering of faradic excitability. Great care is therefore necessary in testing electrically, to prevent the error of ascribing the break, which he supposes to occur in the nervous arc, to a lesion in its sensory instead of its motor portion.

La Folie à Deux.—*Brain* defines folie à deux as a monomania, usually of persecution, happening simultaneously to two individuals, the causes of which are: 1st, Hereditary predisposition; 2d, Intimate and constant contact in daily life; 3d, An exciting cause acting on both.

Dr. Régis, of the Asylum of St. Anne (*Gazette des Hôpitaux*, January 29, 1881), recognized two varieties of this disease. 1st. That in which, of the two individuals who become insane, the one first attacked communicates his insanity to the second who remains on the borderlands of alienation, and may recover on being released from the dominating influence. 2d. More complex and rare, where both are subject to the same form of madness, having been exposed to the same morbid causes and predisposition. The first division has been fully described by Lasègue and Falret, and may be summarized in the following manner: Only one of the two is insane, he having communicated his delusions to the second by a certain moral and intellectual superiority. The individuals have lived in intimate contact. The active agent communicates part of his insanity to the passive; but between the two there is a line of demarcation, the first only being legally insane. Moreover, the latter speedily recovers when removed from the influence of the former. The second division comprises those cases of true *folie à deux* presenting the following characteristics, as observed in five pairs of cases: The two individuals become insane simultaneously. They are hereditarily predisposed to mental alienation. They live in intimate and constant contact. The exciting cause operates on both in the same way and at the same time; the mental manifestations resulting are substantially the same; the hallucinations and delusions are the same. Separation of the two is not attended by beneficial results.

Allochiria—A Peculiar Sensory Disorder—Obersteiner observes (*Brain*, July, 1881) that although great progress has been made of late in the methods of investigation of diseases of the nervous system, yet there is an affection of sensibility which has hitherto escaped special notice. It consists in the fact, that though the sensibility is retained more or less completely, yet the patient is not clear, or is frequently, if not constantly, in error, as to which side of the body has been touched. He would term the phenomenon "sensory allochiria" or contusion of sides. This symptom is so easy to determine, that no long description of method is required. When we test the sensibility of a patient on the leg, for example, and find that the two points of the æsthesiometer are recognized as such at a moderate distance apart, or when a prick or pressure is fairly localized, and yet, as frequently occurs, the irritation is referred to the other side, we have the condition before us. The power of localization as to details is retained, while doubt or error exists as to the side touched, the irritation being commonly referred to the corresponding part of the other limb. The phenomenon is less rare than overlooked, as errors on the part of the patient are apt to be regarded as merely a lapsus verbi. It would be erroneous to look upon allochiria merely as a symptom of great sensory impairment. It must be regarded as a completely distinct symptom by itself. In favor of this view the fact may also be adduced that in very many cases of central neurosis, allochiria is altogether absent, notwithstanding the presence of a marked degree of anæsthesia. Although the writer does not pretend to be in a position to offer a sufficient anatomical and physiological explanation of this peculiar symptom, yet he would advance the following considerations: Apart from an hysterical case, the

allochiria occurred in cases of disease of the spinal cord, mostly in tapes dorsalis. In one case, which was of a different nature (compression—myelitis), there was a marked degeneration of the posterior columns, as shown by the autopsy. It is probable, therefore, that the degeneration of the posterior columns is the cause of the allochiria, though we are not yet able to indicate the more minute changes which lead to it.

The clinical facts recorded also bring out certain physiological points of interest. They show that there is an intimate connection, in a sensory relationship, between corresponding regions of the body, and also that an exactly isolated conduction in the sensory paths of the cord does not exist under all conditions, but under certain circumstances the sensory impulse leaves the accustomed paths and crosses to those of the other side.

A Case of Bursal Swelling of the Wrist Successfully Treated by Division of the Annular Ligament.—Dr. J. E. Copeland has reported a case of bursal swelling of the wrist (*American Journal of Medical Sciences*, July, 1881), in which relief was obtained by resorting to Syme's operation of cutting through the annular ligament. The patient had been heroically treated by a number of practitioners by incisions, punctures, blisters, etc., and all without benefit. The affected wrist measured thirteen and one-fourth inches in circumference, the corresponding wrist of the normal size measured seven and three-fourths inches. There were two firm and hard protuberances over the styloid processes, both of the radius and the ulnar. On manipulating the parts between these protuberances, a sensation as of hard movable bodies impacted in fluid was imparted to the fingers. The operation consisted of dividing the annular ligament by an incision between the tendons of the extensor communis digitorum and the extensor carpi ulnaris muscles. Imbedded in the substance of the enlarged wrist, along the incision, were a number of fibrous or cartilaginous bodies of different sizes, ranging from that of a flax-seed to a small cherry-stone, and of irregular shapes. After the operation the patient was relieved of pain. The wound, treated antiseptically, was kept open and treated upon general principles, until the end of the sixth week after the operation, when the wrist was reduced to eight and one-fourth inches in circumference. Dr. Copeland is inclined to the opinion that operative measures are justifiable in swellings of this character, which strengthens the theory already advanced by Syme.

May Iodide of Potassium Excite Bright's Disease?—With a view to ascertain to some extent the general condition of the kidneys of persons who suffer from late syphilis, as well as to note the effects of antisyphilitic treatment upon these organs, Dr. I. Edmondson Atkinson, of Baltimore, has made a series of observations of cases which occurred in his out-patient service, and in the wards of the University Hospital. Of the seventy cases recorded in the *American Journal of Medical Sciences*, July, 1881, nineteen betrayed evidences of renal disturbance; thirteen being characterized by the presence of albumen in the urine, constantly or at irregular intervals, while in eighteen the microscope revealed in the urine casts of the renal tubules. In twelve cases albumen and tube casts were simultaneously present. The kidneys were affected in very different degrees in the different cases. In few instances were the evidences of kidney disease pronounced and constant. For the most part they were slight and transitory. The cases under observation, where inconsiderable disturbance of the renal organs was associated with the administration of the iodide of potassium, were proportionally numerous. In only a few was it possible to attribute to the drug, with any degree of confidence, a causative influence in exciting the derangement. Although, in the majority of the cases recorded, no definite connection between the iodide ingested and the albumen or tube casts found in the urine could be established, the occurrence of the latter was unexpectedly frequent, and out of all proportion to what is usually supposed to prevail. Dr. Atkinson concludes that while the evil effects of the iodide of potassium upon the kidneys are small and for the most part transitory, the occurrence of more severe alterations is not impossible, nay, is probable. To these evil effects some individuals are more susceptible than others.

On the Influence of Sinapisms on Sensibility.—Adam Kiewicz, in a lecture to the physicians of Cracow, related some interesting observations on the influence of mustard plasters on anæsthesia and normal sensation. In previous researches he had shown that the secretion of sweat was dependent on a centre in the medulla oblongata, acting both through cerebro-spinal and sympathetic tracts. Taking up the subject of "transfer" of sensibility, so well known in connection with metallotherapy, he found that sinapisms produced precisely the same effect as metals.

In a case of organic hemianæsthesia (proved by a post-mortem examination to be dependent on hemorrhage into the lenticular nucleus and internal capsule), he succeeded, by sinapisms applied to the anæsthetic side, in restoring sensibility on the whole of the paralyzed side, lasting several days. The restoration was, however, not permanent. There was no transference.

In the various forms of hysterical anæsthesia the results were variable. In certain irregularly distributed anæsthesia, sinapisms restored sensibility for a greater or less length of time. In a case of hysterical hemianæsthesia, sinapisms produced all the phenomena of transfer. After a few days the old condition returned, but on renewal of the sinapisms sensibility was completely restored without being lost on the other side. In another case of hemianæsthesia and hemiparesia, complete transfer occurred, also with lowering of the temperature, amounting to 5° on the sound side, and corresponding rise on the side formerly anæsthetic.

Following out indications supplied by these observations, he investigated the influence of sinapisms in healthy persons, and found that the sensibility for touch and pain increases on the side of irritation, and diminishes correspondingly on the symmetrically placed point on the other side. Hence it appears these forms of sensibility are bilaterally organized in the nerve-centres, and functionally antagonistic, as shown by the diminution of the one when the other is increased; the result also seems to be that the sense of touch and pain is independent of the richness of the part in nerves, and is a purely qualitative function of the skin. As regards the thermal sense, however, it was found that though it is also rendered finer by sinapisms at the point of irritation, yet it is not correspondingly diminished on the other side. The thermal sense, therefore, does not appear to be bilaterally organized.—*Brain*, July, 1881.

## THE LESSON OF THE BULLET.

The lessons to be learned from the study of the case of President Garfield are not few nor unimportant. Not the least of these is the one bearing upon the courses of bullets fired into the human body. The history of the wound, from the time the latter was inflicted until its surprising effects were manifested at the autopsy, has served in a special manner to accentuate an error in diagnosis, which is the more deplorable, as it has become so notorious in connection with a patient in the treatment of whom the entire world was interested. The only comfort that can now be taken, however, is in the thought that the mistake was inevitable, and that many useful and practical lessons of experience will grow out of it. It is well known that bullets in striking against bone become deflected in strange courses. While making due allowance for this, the appearance of a pus sinus communicating with the point of entrance of the ball, and passing in the direction of least resistance toward the iliac fossa, misled every one connected with the case. This was a strange instance, in which a long, narrow sinus, only indirectly associated with the original injury, exactly simulated in every essential particular a ball-track. It was in fact the only direction into which a probe could pass with ease, and was the only one which was accessible for exploration. In this respect it is virtually unique as a case of gun-shot injury. It is true burrowing pus-pouches are not uncommon in connection with fractures of the ribs, but, as far as we are able to ascertain, there is no case on record in which a gun-shot wound of these bones gave rise to such a long and narrow channel in such a locality. Considering all the main circumstances connected with the injury, the conclusion would appear to have been inevitable that the missile should have taken precisely the course of the pus sinus. There was no symptom, so far as the wound was concerned, that pointed to any possibility of other direction for the bullet-wound, not even excepting the early nervous phenomena referrable to the side of the scrotum and in the skin of the legs and feet. The history of the case from this standpoint develops a new interest in the study of gun-shot wounds of the ribs, and affords a striking example as to the manner in which an ordinary sinus can apparently take the supposed course of a ball. It brings out in the strongest possible relief one of the elements which must hereafter be taken into account in diagnosticating the extent and direction of gun-shot wounds in these localities.

Again, a new importance must be given to the study of the post-peritoneal region of the loin and the possibilities of the extensive injury which it may suffer from projectiles without compromising life. In saying this much, we assume that the pus-track was the most likely course of a bullet deflected downward, and that being nothing more nor less, the patient should have recovered.

It is quite comforting to know that our London contemporaries generally acknowledge that the error in locating the ball was not only perfectly excusable, but wholly unavoidable; and also that the case was treated throughout on sound surgical principles, with the best of results considering the grave and complicated character of the injury. Their comments are not only generous, but just, and must tend to settle many points which might otherwise be open to much unprofitable discussion.

There apparently was only one thing wanting to make the ante-mortem diagnosis positive, and that was to actually touch the ball. It is safe to say that surgeons will not, in the light of this remarkable case, fail to resort to what is now proved to be the only absolute trustworthy test as to the real locality of any bullet; and failing to satisfy themselves in that particular, to give a becomingly guarded opinion.

### TUBERCULOSIS COMMUNICATED TO INFANTS BY MILK.

We have at various times referred to the question whether tuberculosis can be conveyed to human beings by the milk or flesh of tuberculous cows. There are several views in regard to this matter. Some authorities believe it to be an established fact that tuberculosis can be thus conveyed, considering the two diseases as quite identical. Others assert that bovine tuberculosis is a modified form of human tuberculosis. It may be developed by infection in man, but in this case it gives rise to a characteristic train of symptoms, with anatomical lesions resembling those found in the tuberculous cow. Cases thought to illustrate this "bovine tuberculosis" in human beings have been reported in England by Dr. Creighton.

A third view, which need not greatly conflict with the second, is that advocated by Virchow, whose special investigations of this disease entitle him to

speak with much authority. Virchow believes that the so-called bovine tuberculosis, or pearl disease, differs anatomically and pathologically from human tuberculosis, the lesions being sarcomatous. And he thinks it at least premature to suppose that this former disease can be communicated to human beings by the use of flesh or milk.

There has recently been reported, however, a case which certainly bears strong evidence in favor of the pearl disease being communicable in the way supposed.

Professor Demme, physician to a children's hospital at Berne, had brought to his care an infant about six months old. The child was born of healthy and vigorous parents, and it weighed at birth six and one-half pounds. It had been nursed by its mother for five months, and had during that time doubled its weight, continuing healthy in every way. In the sixth month it was weaned, and received regularly, besides other food, the milk from a single cow. Very soon the infant began to sicken. The abdomen became enlarged. From time to time it had diarrhœa. Examination of the thoracic organs revealed no signs of disease. Prof. Demme prescribed the most careful and nutritious diet, adding to the regular amount of milk, beef-juice, brandy, etc. The patient continued to lose flesh, however, and died in about four months. Autopsy revealed tuberculous lesions in the intestine, most marked in the jejunum and ileum. The lungs and meninges were normal.

Two months later the cow from which the milk for the infant had been obtained died. On opening its body the lesions of the pearl disease were found to be strikingly developed.

As the family of the child was perfectly healthy, including two older brothers, the case looks somewhat like one of tuberculous infection. It is important at least to record such histories. There may in time be enough evidence secured to enable positive opinions to be expressed. And this case is sufficient to be a warning to physicians that they learn something about the health of the cow when its milk alone is used by an infant patient.

### THE SANITARY EXHIBITION IN NEW JERSEY.

THE Sanitary Exhibition, at the State Fair, under the direction of the New Jersey State Board of Health, was an encouraging success. The display of sanitary appliances was not so large as one would wish, yet it was sufficient to warrant making it a feature of the Fair in the future. It was undoubtedly useful as a means for educating the people in sanitary matters. At least ten thousand people visited the building. The department of sanitary plumbing was very full, and the people had ample opportunity for becoming acquainted with the mysteries of traps and soil-pipes.

Professor Leeds, of the Stevens Institute, made an exhibition of over four hundred samples of foods and drugs that he had analyzed. Each sample was displayed in a bottle bearing a label on which was stated the results of the analysis. It is interesting to know that the adulterants used in this country are the same as are employed in England and described by the English analysts. Examples of poisonous adulterations are very rare; only one specimen was shown in Dr. Leeds' collection, and that was in pickles. Traces of copper were found. Adulteration is a commercial and not a sanitary problem.

### THE MATERIA MEDICA SOCIETY.

IN another column we give an extract of an address read at a recent meeting of this new society—which at present numbers fourteen members, all of whom are well-known professional gentlemen of this city—each of whom is pledged to provide an appropriate essay in turn. The society has but two officers, a president and a secretary, who are selected by lot instead of ballot. There are no honorary or corresponding members. Candidates for admission must present an appropriate and acceptable thesis prior to being balloted for. Evidently the society means work, and from our knowledge of its personnel we have every reason to expect work of a superior quality.

### REGULATIONS FOR PLUMBERS.

IT is a matter for much congratulation that the Health Board of this City has not only secured the licensing of plumbers, but has duly adopted a stringent and comprehensive code for their guidance. In the list of requirements recently published, every necessary point referring to proper drainage is insisted upon, as well as the character of workmanship calculated to insure it. It is distinctly stated what the diameter, construction, and material of pipes shall be; how the proper ventilation of them is to be effected; what means shall be adopted to insure the escape of sewer-gas from the roof; and how the joints of pipes can be safely and effectually soldered. The plumber need no longer plead ignorance as to what is justly required of him, and when not properly watched may be thrown upon his honor to do his duty. It becomes a serious question whether or no the Health Board will be able to restrict the majority of plumbers to straightforward work. Inspectors are out of the question. If they were possible, no one could undertake to follow the dodging into darkened shafts, or appreciate intelligently the developments of their costly tallow dips. We confess to a dark suspicion that, despite the attempts at radical reform, there will not in the long run be any perceptible lessening of plumbers' bills. Until the Board can regulate the price of lead, charcoal, candles, and helpers' time, the main utility of the craft will still be triumphantly vindicated.

# Reports of Societies.

## THE AMERICAN GYNECOLOGICAL SOCIETY.

*Sixth Annual Meeting, Held in New York, September 21, 22, and 23, 1881.*

WEDNESDAY, SEPTEMBER 21ST—FIRST DAY—MORNING SESSION.

THE Society met at the Library Hall of the New York Academy of Medicine, and was called to order at 10 A.M. by the First Vice-President, DR. THADDEUS A. REAMY, of Cincinnati.

DR. WM. H. BYFORD, of Chicago, the President, on account of sickness, was unable to be present.

THE ADDRESS OF WELCOME

was delivered by FORDYCE BARKER, M.D., LL.D., President of the New York Academy of Medicine, who gave a brief résumé of the history of the organization, spoke of the fruits of its labors, seen in the five volumes of Transactions, was referred to the frank and cordial manner in which the pre-eminence of American gynecologists was conceded by the most distinguished men from all the European nationalities represented at the International Congress, notwithstanding the differences of opinion in regard to many special subjects.

The address closed with the following words: "I esteem it as a high honor, as well as a great pleasure now, in behalf of the New York Academy of Medicine, to welcome the American Gynecological Society at its sixth annual meeting to this hall. The presence of such numbers to greet you at its opening warrants me also in welcoming you in behalf of the whole profession of this city, and in expressing the hope that its three days' session may be memorable in the future, not only as a refreshing season, but as an era in its history, from its contributions and additions to our science and our art.

"As our society bears a national name, I may be pardoned for an allusion to one striking contrast as regards the associations which surround us, and must, in a degree, affect us all at the present time, as compared with those at our first gathering in this hall. Then the country was celebrating the first centennial of its existence as a nation. Now the whole country—North, South, East, and West equally—is clouded by a national sorrow which annihilates the bitterness of party feeling and unites all in a common bond of sympathy and mourning. On two occasions before the country has felt the shock which must follow the death of its President from disease. Another fell by the hands of an insane fanatic at the close of a fearful struggle between different sections of the country, and his death was lamented as a great public calamity by both parties in the contest which had just terminated. But no one ever could have anticipated the possibility that one chosen by the suffrages of a free and reunited people, bound together more closely than ever by the ties of common interest and sympathy, could be in danger of his life from an assassin. If the presence of such events casts a deep shadow of sadness over our festive reunions, it should not diminish our zeal for work in the noble aims to which the society is devoted."

ACUTE HYPERÆSTHESIA OF THE PERITONEUM, EITHER CIRCUMSCRIBED OR DIFFUSED, FOLLOWING MINOR GYNECOLOGICAL OPERATIONS AND MANIPULATIONS.

DR. SAMUEL C. BUSEY, of Washington, D.C., sent a paper on the above subject, and reported a case which represented the type of a class occasionally occurring in females, of which the predominant clinical feature is pain and tenderness diffused over the entire area of the abdomen, unaccompanied with the other usual symptoms of inflammation. The paper was read by Dr. Jos. Taber Johnson, of Washington.

One week previous to the expected menstruation, he introduced without difficulty a laminaria tent about the size of an ordinary metallic knitting-needle. Soon after leaving the house the pain began and rapidly increased in intensity, reaching in about forty minutes, when the tent was withdrawn by her husband, a degree of agony never before experienced. The pain began in the womb, and was speedily diffused over the entire area of the abdomen. The sensitiveness was so acute that the weight of the bed-clothing could not be borne. Every jar of the bedstead or of the floor of the apartment increased her suffering. Coldness of the extremities, pallor of the face, nausea and vomiting, and vesical irritability took place apparently simultaneously with the hyperæsthetic phenomena. A twenty-drop dose of chlorodyne was given and was repeated, and fomentations were applied to the abdomen. The next day she was quite relieved, a slight feeling of soreness in the middle epigastrium only remaining. Tympanites and fever were absent. What is the pathological condition? The absence of fever, tympanites, and effusion exclude inflammation.

If inflammation is excluded, would not the freedom from fever, rapid subsidence of symptoms, and absence of consequent conditions, bar the hypothesis of simple inflammatory hyperæmia? The theory of inflammation is, however, unsatisfactory, and in the above case would prove too much, inasmuch as it would attribute the cure to the efficacy of a moderate and evanescent narcotic, and pretermit the more logical conclusion, that the speedy relief was due to the prompt removal of the cause. If the withdrawal of the tent was, in fact, the remedy, then the assemblage of symptoms was manifestly a neurosis, finding its explanation in the excessive sensibility of the peripheric endings of the sympathetic nerves supplying the part irritated, and in the morbidly heightened excitability of the receptive nerve-centres, which was so great as to produce reflexly the gastric, cardiac, and vasomotor disturbances.

The clinical picture presented represents, probably, an observation of unusual intensity; but the gradations of suffering, varying from an aggravated to milder forms, sometimes barely sufficiently marked to attract attention, constantly threaten our confidence in the harmlessness of minor gynecological operations and manipulations, and for the time being disturb the equanimity and self-reliance of the most astute diagnostician.

DR. I. E. TAYLOR, of New York, thought the tendency was to look for a local cause, such as introduction of the probe, excessive walking, etc., in explanation of pelvic pain, and to overlook two other prominent causes, namely, hysteria and neuralgia. He then referred to a case in which a patient had suffered from symptoms suggestive of peritonitis on the left side for several years, and yet there was no inflammatory action there whatever. He thought that a distinction should be made between local and

general causes. Malaria was a common general cause for such local manifestations, and such cases, as a rule, readily yielded to quinine. He thought that Dr. Busey's case could be classed among the neuroses.

Dr. Noeggerath, of New York, said that the discussion had brought out several conditions which had been diagnosticated under the name of peritoneal hyperæsthesia. Out of the various forms three distinct conditions could be obtained: 1, True peritonitis; 2, true neuralgia of one or the other tracts of nerves supplying the peritoneum and its contents; and 3, neuralgic affection of the uterus. He regarded the term 'peritoneal hyperæsthesia' as descriptive only of a symptom, and that the cause should be sought for. He then gave the history of a case in which an apparently healthy young girl became suddenly frightened, was soon afterward attacked with violent abdominal pain, and died without other symptoms. At autopsy a teaspoonful or so of serous exudation was found in the peritoneal cavity, near the uterus on each side, and on examination with the microscope it was found to be crowded with cells belonging to the Fallopian tube. The tubes were then examined and found to be the seat of a catarrh, probably of long standing. The explanation then was that the fright had given rise to expulsion of the septic matter from the Fallopian tubes into the peritoneal cavity. Had not a careful examination been made, the case might have been regarded as one of peritoneal hyperæsthesia, instead of peritonitis, which it actually was. If so difficult to find the cause of death at autopsy, how natural that a large number of truly inflammatory cases should be called neuralgic during life!

Dr. J. Marion Sims, of New York, had seen many such cases as described by Dr. Busey, but he had not associated them with peritonitis. He had always regarded the condition as a neurosis, which would disappear within a few hours if treated with opiates. He had seen these symptoms develop after the introduction of a tent, division of the cervix, attending menstruation, etc. He was not quite certain that the term 'hyperæsthesia of the peritoneum' was a proper one, as the hyperæsthesia usually existed all over the abdomen.

Dr. Trask, of Astoria, N. Y., believed the term 'acute hyperæsthesia' to be a better one than 'neuralgia of the peritoneum.' He also believed that the condition could be developed by general as well as local causes, and cited a case in which it was evidently due to sewer-gas poisoning.

Dr. Van De Warker, Dr. Engelmann, and Dr. Emmet further discussed the paper, and thought that the term 'acute hyperæsthesia' might mislead. The paper was also discussed by Dr. Reeve, of Dayton, O., and Dr. F. H. Campbell, of Augusta, Ga.

Dr. H. J. Garrigues, of New York, then read a paper entitled

EXPLORATORY PUNCTURE OF THE ABDOMEN.

The author had examined the fluid of a large number of ovarian cysts and compared it with that found in other abdominal tumors and with fluid from collections in other parts of the body.

Myxoid proliferous cystoma, being by far the most common variety of ovarian cysts, was discussed in detail. As a rule the physical characters are so marked that the fluid can be recognized by its mere appearance. The most important physical character is the viscidity, but it may be absent in ovarian cysts and found in other cysts.

Ovarian fluid does not contain any characteristic chemical element. The coagulability has a certain diagnostic value. The test claimed as characteristic for ovarian cysts, that the coagulum is redissolved in boiling acetic acid, is utterly unreliable.

Of much greater importance is the microscopical examination. It is only by studying the cyst-wall that the nature of the formed elements found in cyst fluid can be understood. The most important elements are columnar epithelial cells seen in side view. The corpuscles, known as Drysdale's granular ovarian cells, are merely nuclei in fatty degeneration, and have no diagnostic value. The author has been able to follow their origin from the time when they are yet embedded in the epithelial cells on the inside of the cyst.

The spindle-shaped cells, smooth muscle-fibres, which have been claimed to be pathognomonic of fibro-cysts, the author has found in the fluid of an ovarian cyst. There is no pathognomonic morphological element in ovarian cyst fluid, but in the great majority of cases ovarian fluid can be distinguished from all others by the mere examination, and, combined with the data gained by the history and physical examination of the patient, the examination of the fluid is of paramount diagnostic value.

There was no means of distinguishing a cyst of the broad ligament from that of the ovary by the nature of the contents.

An instantaneous and complete coagulability is characteristic of uterine fibrocyst, but has only been found in a minority of cases. Columnar epithelial cells have never been found in uterine fibro-cysts.

The advantages to be gained by examination of the fluid are so great that it ought to be undertaken in every case before operation. By using a fine canula and aspirator, and pushing the trocar in slowly, the danger of wounding vessels is exceedingly small. The real danger is from carrying septic matter into the interior of the body, and that could be avoided by antiseptic precautions. The whole amount of fluid found in the cavity opened ought to be withdrawn in order to avoid the pouring out of the remainder into the peritoneal cavity. After the operation the patient ought to stay four days in bed, in order to further guard her against peritonitis.

Dr. T. M. Drysdale, of Philadelphia, differed with the author of the paper, and still adheres to the pathognomonic value of the "ovarian cell," or perhaps better, the "ovarian corpuscle."

Dr. Leopold Meyer, of Copenhagen, a member by invitation, was of the opinion that tapping is not so frequently resorted to as Dr. Garrigues seemed to think it should be. He believed that the cases in which tapping was necessary to diagnosis were infrequent.

Dr. H. P. C. Wilson, of Baltimore, thought, if there was grave doubt concerning diagnosis, the exploratory puncture might be available; but he felt sure that tapping uniformly diminished the chances of success in a subsequent ovariotomy.

Dr. T. A. Emmet, of New York, thought it should be done only as an exception to the rule.

Dr. Barker, of New York, referred to a case in which, at autopsy, it was found that a mesenteric vein had been opened by the trocar, and the peritoneal cavity was filled with blood.

Dr. Lyman, of Boston, was inclined to agree with Dr. Meyer.

Dr. Dunlap, of Springfield, O., thought that, in rare cases, tapping might be necessary in order to complete the diagnosis by microscopical examination.

Dr. Campbell, of Augusta, Ga., suggested that Dr. Garrigues referred to exploratory puncture, or tapping, for purposes of diagnosis, the operation being done with a small needle, and special precautions being taken that the operation do no injury.

Dr. Emmet reminded Dr. Campbell that death had occurred after the use of the hypodermic needle for purposes of diagnosis, and he had seen inflammation of the sac follow the withdrawal of not more than half a drachm of fluid.

Dr. Kimball, of Lowell, avoided tapping if possible; yet he could recall only a single case in which bad results had followed the operation.

Dr. Reeve, of Dayton, O., thought that tapping should be resorted to in exceptional cases.

The discussion was made the special order for the afternoon session.

---

Wednesday—First Day—Afternoon Session.

The society was called to order at 3 P.M. by Dr. Reamy, and the discussion on

EXPLORATORY PUNCTURE OF THE ABDOMEN

was renewed by Dr. G. J. Engelmann, of St. Louis, who, as a means of diagnosis, regarded the operation as an important one, and one which might be necessary in certain cases; perhaps not so often, however, as one might be led to infer from Dr. Garrigues' paper. The exploratory puncture had, perhaps, more scientific interest than practical importance.

Dr. Howard, of Baltimore, avoided the operation if it was possible to do so, and yet the life of the patient had doubtless been saved by the procedure.

Dr. Drysdale, of Philadelphia, had had large experience in tapping, and he was unable to recall a single case in which a fatal result followed the operation.

Perhaps the method had something to do with the results, namely: Place the patient upon the back, in the semi-recumbent position, with the head and shoulders well-supported, and with a sheet supporting the abdomen, as the fluid flows away. He regarded it as a very dangerous proceeding to tap and only partially evacuate the cyst.

Dr. Dunlap regarded manipulation of the tumor for purposes of diagnosis immediately after tapping as a very dangerous procedure.

The discussion was continued by Drs. Chadwick, of Boston, Noeggerath, of New York, and closed by Dr. Garrigues.

The title of the next paper was

NOTES ON CASES OF PELVIC EFFUSION RESULTING IN ABSCESS,

by Dr. H. G. Lyman, of Boston. From 1875 to 1880, inclusive, one hundred and forty-six cases of pelvic effusion had been treated by himself and his colleagues in the Boston City Hospital. These cases were admitted at all stages of the disease, and of them there were forty-one which were already at the time of admission, or soon afterward became, cases of pelvic abscess. It was not the design of his paper to enter upon any elaborate discussion of the pathology of the disease, but to direct the attention of the society more particularly to the following considerations:

*First.*—The necessity of a more general recognition by the profession at large of the fact that pelvic effusions were of extremely frequent occurrence, that very often they were not recognized, through error in diagnosis, and especially from the fact that, when arising from pelvic peritonitis, they were commonly absorbed, leaving only a focus of induration.

*Second.*—The extreme importance of recognizing in these effusions the earliest advent of suppuration, and in doubtful cases the propriety of a resort to the aspirator, as being the least of two evils.

*Third.*—Suppuration being recognized, the importance of giving early exit to the pus per vaginam, if by any means this could be safely accomplished, before the danger was incurred of its extension to the surrounding tissues, with long-continued and exhausting discharges, too often resulting fatally.

Dr. A. H. Smith, of Philadelphia, regarded the practical point, namely, early opening such abscesses per vaginam, as an exceedingly important one. Under proper antiseptic precautions, he thought the risk was trivial, while the dangers from suppuration and spread of pus were necessarily very great.

Dr. Ellwood Wilson, of Philadelphia, had not attempted to interfere surgically until after the abscess had been well developed.

Dr. Fordyce Barker, of New York, had seen the aspect of the case changed entirely and in the most favorable manner by the introduction of a hypodermic needle and drawing off one or two drachms of serum. He advocated early operative procedure.

Dr. Paul F. Mundé, of New York, advocated early operative procedure for the removal of pus.

Dr. Van De Warker, of Syracuse, N. Y., believed that the spontaneous escape of pus through the bladder or the rectum was not a true opening, but that a pus cavity was left which, as a rule, never evacuated itself. He thought it was sometimes very important to open such abscesses, late as well as early.

Dr. Emmet, of New York, a few years ago did not hesitate to use the trocar, but his experience had made him more conservative, and he now hesitates before thrusting in even a hypodermic needle.

---

Thursday, September 22d—Second Day—Morning Session.

The society was called to order by Dr. Reamy, at 9.30 A.M. The first paper was read by Dr. N. Bozeman, of New York, and entitled:

GENITAL RENOVATION, PARTICULARLY BY KOLPOSTENOTOMY AND KOLPOECPETASIS, IN URINARY AND FECAL FISTULES.

Dr. Bozeman proposed the term genital "anakainosis," meaning the opposite of genital "kleisis," for the operation practised by him (since 1855), by renewing, and, as far as possible, restoring the vagina to its natural dimensions, and by closure of fistules successfully in the vulvo-vaginal and uterine tract, without interference with its normal functions.

As an important part of genital "anakainosis" he performs "ephelkosis" (the process or act of pulling down), to make the uterus subservient to the closure of large defects in the vesico-vaginal or recto-vaginal septa. This operation he designates "hysteroephelkosis." In cases where there are defects, losses of substance in the female bladder, this organ, from disuse, remains folded up, contracted, and distorted, and for this pathological condition, found to be present more or less in all cases of vesico-vaginal, or vesico-utero-vaginal, or urethro-utero-vesico-vaginal fistules, he uses the word cystostellosis, to contract, to fold

up, as a companion word to kolpostenosis, the cicatricial narrowing of the vagina; and, as a term designating the operative procedure of cutting into cicatricial bands, adhesions, contractions, tortuosities and abnormal narrowings of the vagina, the word "kolpostenotomy" is used. Kolpoecpetasis is the opening up of the vagina by gradual dilatation with metallic or hard-rubber cylinders, or oiled-silk bags filled with bits of sponges. These operations on the female genito-urinary tract are of the greatest importance and value in maintaining the genital tract *without unsexing the unfortunate woman* who is suffering from a fistule not easily accessible to the surgeon's instruments, and for the cure of which the late Prof. Simon, of Heidelberg, proposed and practised the shutting up of the vagina—"kolpokleisis"—an operation which Dr. Bozeman condemns as unjustifiable.

The objections to kolpokleisis, besides the unsexing of the woman, are the formation of calculi, the supervention of cystitis, nephritis, pyelitis, etc. In Dr. Hergott's four cases the mortality as an immediate result of his operations was twenty-five per cent.

Dr. Bozeman then relates cases in which kolpostenosis existed and pregnancy took place; where he saved the life of the child and possibly the mother's, by kolpostenotomy and kolpoecpetasis. He had also cured cases where both recto-vaginal and vesico-vaginal fistules existed in the same woman, by kolpostenotomy and kolpoecpetasis. From extensive observation and from his conviction, already obtained by personal experience in 1870, that kolpokleisis was an exceedingly dangerous and unwarrantable operation, he recommended in preference genital anakainosis by kolpostenotomy and kolpoecpetasis. The doctor then presented a tabular statement of fourteen cases, treated by genital anakainosis in the Woman's Hospital, together with a statement of his one hundred and twenty cases of fistules, and a comparison of their results with those of Prof. Simon.

Of the fourteen cases there were: 1, urethro-vaginal fistule; 2, urethro-vesico-vaginal fistules; 3, vesico-vaginal fistules; 6, vesico-utero-vaginal fistules; 1, vesico-utero-cervical fistule; 1, urethro-utero-vesico-vaginal fistule.

For the 14 fistules in 14 patients, 18 operations were performed, and 13 fistules in 13 patients were cured with preservation of the vagina; 1 patient with 1 fistule left his service after preparatory work.

Nearly all of these cases were of an aggravated character: one with total destruction of the vesico-vaginal septum, and two with incarcerated cervices uteri in the bladder.

The percentage of his success (92.85 per cent.) was higher than Prof. Simon's, who operated on 118 fistules in 105 patients and claimed 92 cures, 87.62 per cent., including kolpokleidic cures, and cures alone by uniting the borders of the fistules. Dr. Bozeman then gave his own statistics of operations performed since 1855, when he adopted his new method of genital anakainosis, founded upon the principles of kolpostenotomy, kolpoecpetasis, cystoecpetasis, hysteroephelkosis, and splint-formed suture.

There were 150 fistules in 120 patients. The number of operations performed was 181. Of these cases, 101 were cured by uniting the borders of the fistules, with preservation of vagina=84.16 per cent.; 2 were treated and ameliorated by genital kleisis=1.66 per cent.; operations for each case cured=1.48 per cent.; 4 deaths=3.33 per cent.

Dr. E. Van de Warker, of Syracuse, N. Y., then read a paper on

FORCIBLE ELONGATION OF PELVIC ADHESIONS.

The interest in the paper centered in the fact that the plan of treatment was brought forward for the relief of symptoms in a certain class of cases; one marked symptom in this special class being pain in defecation. His method of operating was—dealing specially with posterior adhesions—to etherize the patient, and then with any convenient uterine dilator quickly and forcibly dilate the cervical canal. He then introduced a sound of large size. That which he employed in the cases reported was formed from a very large-sized male bougie, and with it he turned the uterus forward, so that the fundus could be felt above the pubes, and at the same time he forced the organ more or less upward and forward, which, in some instances, could be done to the extent of an inch or more. The after-treatment consisted in keeping the patient in bed. No supports of any kind were needed; in fact, they were contra-indicated. If the adhesions showed a disposition to contract, they would not be prevented by the use of any support. The operation might be repeated at the end of two or three months, if thought necessary. A special point he insisted upon in the treatment was that all operative procedure should be completed at one time. He had operated in four cases; in the last case the patient was not benefited.

Dr. Bozeman, of New York, had been accustomed to treat such cases, retroflexion or retroversion, with fixation, by using cylinders of sponges in the vagina. He had also treated them by columning the vagina, which consists simply in placing the patient in the knee-chest position, and making these columns in the vagina, packing it down to the pubic arch and the perineum. At the end of twenty-four or thirty-six hours the sponges are removed by the patient, the douche used for forty-eight hours, and then the columns renewed. The steady pressure would gradually increase the length of the posterior wall of the vagina, and finally restore the uterus to its natural position.

Dr. Emmet asked Dr. Bozeman if the plan of packing the vagina with sponges had been attended by any bad consequences.

Dr. Bozeman said that in not a single case had any serious complications arisen, and he had been practising the method for more than twenty years.

Dr. Campbell thought that the retroversion or retroflexion with fixation could be overcome by mechanical pressure, and to accomplish it, he had been in the habit of using an ordinary ring pessary, first applying one of moderate size, and increasing the size as the plastic material yielded and gave increased space. He thought that in many cases cure could be effected, if the patient would every night assume the knee-chest position and maintain it for some time.

Dr. J. Marion Sims had not seen twenty cases of permanent adhesions, in the class of cases referred to, in his whole life. When his friends in London and here spoke of elevating the retroverted uterus by mechanical pressure, they had been mistaken in supposing that there were any adhesions. Dr. Sims then described his own instrument devised for restoring the uterus to its proper position, and regarded it as far superior to Simpson's sound.

Dr. Wilson, of Baltimore, said that he had not been able, under any circumstances, to replace the

retroverted uterus held in position by adhesions, and keep it in position.

Dr. A. Reeves Jackson, of Chicago, was convinced that the practice advocated by Dr. Van De Warker would be ineffectual, or, if not, that it was necessarily dangerous.

Dr. Chadwick, of Boston, had been in the habit of raising the retroverted and adherent womb for several years, and in perhaps five thousand cases in dispensary practice he had seen probably six or seven hundred in which there was fixation of the uterus in the retroverted position, with more or less adhesions. It had been his practice habitually to raise the uterus in such cases, provided there was no tenderness, but he had not used any force. And in all the cases he had given marked relief to symptoms. But he never used the sound for replacing the womb, and preferred to introduce a stem and then manipulate the organ bimanually.

Dr. A. H. Smith, of Philadelphia, thought that the discussion could be simplified by making a distinction between fixation and adhesion of the uterus; for there might be fixation without adhesion—fixation from habit, for example, such as exists in a patient who has carried a retroverted womb for years, not having had the malposition, which occurred accidentally, rectified. Such uteri he had been in the habit of replacing by mechanical force. But in those cases he had not been able to retain the uterus in position without some mechanical support, and latterly he had used the intra-uterine stem-pessary, supporting it, after the organ had become accustomed to the stem, with a retroversion pessary, and happy results had been obtained.

Dr. Goodell thought there was a mistaken idea somewhere as to the meaning of the term adhesion. For Dr. Chadwick had found adhesions in six or seven hundred cases out of five thousand, and Dr. Sims had met with adhesions not more than twenty times during his entire practice. He agreed with Dr. Sims, and further said that he had not seen ten cases in which he had encountered adhesion bands. He had, constantly, cases sent to him with the statement that there were adhesions which held the uterus backward, but in the vast majority of them he had simply found the organ imprisoned in the utero-sacral ligaments. He regarded Dr. Van De Warker's practice as exceedingly hazardous.

The discussion was continued by Dr. Mundé, Engelmann, and Lyman, and closed by Dr. Van De Warker.

### THE PRESIDENT'S ANNUAL ADDRESS.

The hour having arrived for the delivery of the President's annual address, it was read by the Secretary, Dr. Chadwick. After thanking the society for the honor which it had conferred upon him, Dr. Byford proceeded to speak of gynecology as an associated branch of medicine, and believed that the appellation "specialty" should not be applied to it. He regarded the American Gynecological Society as the legitimate outgrowth of the rapid strides which had been made in this department of medicine, especially in contrast with what has more usually been called the department of Surgery. He then referred to the organization of the society and its early history. The social enjoyments of the society he regarded as not the least important. He believed that the experiment of meeting in the West had proved not to be a safe one, but that the annual meetings of the society should be held in some of the important cities on the sea-board. Dr. Byford then referred to the work which had been done by the society, as represented by its five volumes of transactions, and of the special value in which they were held and appreciated, not only at home, but abroad. The chief portion of his address was devoted to the consideration of the subject of a McDowell fund, in honor of the late Ephraim McDowell; a fund, the interest of which could be expended for prize essays, and he suggested that the American Gynecological Society should be its custodian. The recognition which the profession had already given to the genius and labors of Ephraim McDowell had been chiefly confined to the medical profession of the State of Kentucky. His plan proposed that all interested in ovariotomy should have an opportunity to contribute to this fund, and one feature of his plan was, that every ovariotomist should contribute either five or ten dollars of his fees from each operation. Whether the plan which he suggested should be matured and put into operation or not, was not a matter of so much interest to him as that some plan, well devised and carefully matured, should be put into operation for the more substantial recognition of him who may justly be called the father of ovariotomy. The address closed with congratulatory remarks upon the success which the Society had already obtained in the performance of its special work.

Dr. Isaac E. Taylor, of New York, then read a paper entitled

### ESTHIOMENE; OR, LUPUS OF THE VULVA.

The paper contained the history of seven cases, and was accompanied with colored illustrations. Although the disease had long been recognized, it was rarely seen upon the genital organs. When it occurred in that region, the pathological changes did not differ from those present when it occurred upon the face or other parts of the body. Of the seven cases reported, two were cured, two relieved, two unrelieved, and one patient died. The essential pathology he regarded as an outgrowth of the cutis alone. It was not contagious, it was not inoculable. With reference to the treatment, it was essentially local, and he had used the pernitrate of mercury, curetting, excision of the elevations, etc. Unguents should be avoided. The special feature in the local treatment was, that harm should not be done to the tissues below.

Dr. John Byrne, of Brooklyn, said that his method of treatment was purely surgical, and consisted in excising the mass thoroughly with the cautery, and then thoroughly cauterizing all subjacent tissue. When so done, the parts had granulated and healed kindly, and the process of repair had gone on without difficulty.

The paper was further discussed by Dr. Kimball, of Lowell, Dr. Barker, of New York, and Dr. Wilson, of Baltimore.

The society then adjourned, to meet at 3 P.M.

---

### Thursday—Second Day—Afternoon Session.

The society was called to order at 3 P.M. by the Second Vice-President, Dr. H. F. Campbell, of Augusta, Ga.

Dr. William Goodell, of Philadelphia, then read a paper on

### BURSTING CYSTS OF THE ABDOMEN.

He made special reference to cysts which, of their own accord, burst and refilled. Illustrative cases

were given: first, that of a patient who had an abdominal tumor from which she was greatly oppressed with a bursting sensation. It was aspirated, and eight quarts of blood-stained fluid were withdrawn. It was subsequently aspirated, and the fluid withdrawn was of a greenish color. He regarded it as a monocyst of the right ovary. Subsequently a day was appointed for aspiration, but before the operation was performed the cyst burst spontaneously. On four occasions it burst spontaneously, and was tapped probably about a dozen times. Finally the condition of the patient became such as to render the removal of the tumor necessary. The cyst-wall was found to be exceedingly thin and of a beautiful conjunctival blue color. The tumor was ostensibly that of cystic degeneration of the ovary, but, upon more careful examination after its removal, it was proven to be ovarian and parovarian. The author gave some statistics of the great mortality of bursting ovarian cysts. A collection of ninety-seven cases was cited in which there were forty-six deaths and fifty-one recoveries. When, however, parovarian cysts ruptured, the fluid was so bland that fatal results did not usually occur. He had been able to find the record of only one fatal case. While tapping may cure parovarian cysts, spontaneous rupture does not always terminate so, for the cyst is apt to refill. In five cases which he had tapped, the fluid was clear like spring water, and in none had the cyst refilled. Cysts of the parovarium are almost always unilocular. They may be bilocular or multilocular, but the latter are very rare. It is questionable whether a true unilocular cyst of the ovary has ever existed.

Dr. H. J. Garrigues, of New York, remarked, that among some of the most scientific gynecologists it had become quite fashionable of late to substitute the term cyst of the parovaria for the term in common use, cyst of the broad ligament. He doubted the advantage of the substitution. Of course the parovaria can become the seat of a true cyst, but cysts might also occur, and very frequently did, along the course of the Fallopian tube, and he thought it was impossible to say, when we had to deal with such a cyst, whether it was parovarian or not, if it had been developed in the outer part of the broad ligament. He believed, therefore, that it would be as well to retain the old term. It was extremely difficult to distinguish anatomically with certainty between a cyst of the broad ligament and an ovarian cyst; or an ovarian cyst and an extraovarian. Dr. Garrigues had seen a monocyst of the ovary, and had no doubt that it existed, but it was exceedingly rare.

The paper was discussed by Drs. Barker and Sims, of New York; Kimball, of Lowell; Dunlap, of Springfield, O.; Wilson, of Baltimore; Drysdale, of Philadelphia; Reamy, of Cincinnati; and Kinloch, of South Carolina; all of whom gave the history of cases in which spontaneous rupture of ovarian cysts occurred. The discussion was closed by Dr. Goodell, who could not resist the conclusion that some of the gentlemen had mistaken parovarian for ovarian cyst.

Dr. H. F. Campbell, of Augusta, Ga., read a paper entitled

ERYSIPELAS IN CHILD-BED WITHOUT PUERPERAL PERITONITIS.

Heretofore it had been the practice that a previous or recent attendance by a physician upon a case of puerperal fever, or puerperal peritonitis, debarred him from attending any cases of labor, through fear of manual transmission of the poison of the disease to the lying-in women. It had also been regarded as scarcely less obnoxious for the physician or nurse to attend upon a case of erysipelas and subsequently to attend upon a lying-in woman. Dr. Campbell then proceeded to relate the history of a case in which a woman had well-marked facial erysipelas, and subsequently passed through labor without complication, and recovered without a single unfavorable symptom. The question is, Are the great apprehensions about coming in contact with cases of erysipelas and subsequently attending cases of confinement well based? The present case would seem to deny that principle entirely. He reported it for the purpose of obtaining an expression of opinion of the Fellows of the Society.

Dr. M. Putnam-Jacobi, of New York, suggested that Dr. Campbell's case could be explained on the ground that erysipelas is primarily a disease of the lymphatic system, and as there was no anatomical connection between the erysipelas of the face and the uterus, the wounded surface of the latter was not really exposed to the poison.

Dr. Goodell, of Philadelphia, believed that there is an intimate relation between erysipelas and puerperal fever, but to have that relation developed he also believed it to be necessary to have the phlegmonous variety of erysipelas.

Dr. Wilson, of Baltimore, had never been able, in his own private practice, to trace a case of puerperal fever to a case of erysipelas as the cause. He had traced one case to scarlet fever.

Dr. Smith, of Philadelphia, thought that thorough disinfection of the hands would prevent the physician from communicating the disease.

Dr. Lyman, of Boston, did not attend cases of labor soon after attending cases of erysipelas.

Dr. Ellwood Wilson, of Philadelphia, thought that thorough disinfection of the hands and clothing was almost invariably certain to exempt one from conveying the poison of erysipelas or scarlet fever.

Dr. Barker, of New York, believed that the intimate relationship between puerperal fever and erysipelas has been as firmly established as any fact in medicine. It was possible that with proper disinfection a physician might attend a case of simple facial erysipelas, and subsequently attend a case of confinement without harm; but the risk should not be taken with reference to cases of phlegmonous erysipelas or surgical erysipelas with suppuration.

The society then adjourned, to meet on Friday at 10.30 A.M.

---

FRIDAY, SEPTEMBER 23D—THIRD DAY—MORNING SESSION.

The society was called to order at 11 A.M. by Dr. Campbell.

THE EXPANSION OF THE BLADDER OVER THE SURFACE OF ABDOMINAL TUMORS, AND ITS ATTACHMENT TO THEM OR TO THE ABDOMINAL WALLS, AS A COMPLICATION OF LAPAROTOMY,

was the title of a paper then read by Dr. T. Gaillard Thomas, of New York. It was a most striking and noteworthy fact that, notwithstanding the amount of careful study and prolonged investigation for the perfection of a capital surgical procedure, there were even yet special points which made their appearance, and which thus far had almost entirely escaped attention. An illustration of this statement could be found in the complication to which he pro-

posed to direct the attention of the Society, namely, the expansion of the bladder over the surface of abdominal tumors, and its firm adhesion to them or the abdominal walls. By the term expansion he meant that which consists in an apron-like spreading of the bladder, which is trebled or quadrupled in size over the whole of the anterior surface of the tumor from the umbilicus, or a point above it, downward to the pelvis. The literature of the subject had furnished us with seven cases of this character, in all of which a fatal issue had been the consequence of the adhesion, either from direct injury done to the bladder—the surgeon not recognizing the complication—or from failure to remove the tumor on account of its existence; and yet in no work with which he was acquainted was this condition systematically dealt with. As to the pathology of the condition, little need be said.

Dr. Thomas then proceeded to give a short sketch of all the cases of this kind of which he had been able to obtain any history, closing with a more complete account of one which had recently occurred in his own practice, and which had suggested the paper. The eighth case embodied Dr. Thomas' personal experience in dealing with this complication. Miss C——, thirty-eight years of age, a native of Canada, entered his service in the Woman's Hospital in November, 1880, on account of a large multilocular ovarian tumor, and on the sixth of that month she was submitted to operation. An incision about three and one-half inches in length was made in the median line, and the tumor was seen presenting a peculiar appearance, which arrested his hand just as he was about to plunge in the trocar and canula. He then enlarged the abdominal incision, and was led to suspect that the mass covering the tumor might be the bladder. He endeavored to settle this point by passing a long catheter, but the tumor pressed so firmly against the pubes that it could not be introduced beyond that point. Becoming convinced more and more that he had to deal with a case of extensive vesical adhesion, he tried to determine the points at which the bladder was attached to the tumor, but he was unable to do so, so completely did the bladder seem united with the tumor. It occurred to him that if he could tell exactly where the upward limits of the attached viscus were, he would be able to cut it away, and to accomplish this he decided to go directly through the anterior wall of the bladder, so that one or two fingers could be inserted. Such an incision was accordingly made, and he passed the index finger of the left hand into the bladder, and was able by so doing to learn exactly the extent of the viscus, and to cut down upon the tumor, severing the strong attachment. In this way, exposing with the finger or fingers, cutting down at the appropriate point, tearing adhesions after cutting, he soon freed the bladder entirely from its attachments. A great deal of hemorrhage followed, and quite a number of ligatures had to be applied to bleeding vessels. After this the trocar was plunged into the tumor, and it was removed in the usual way, its pedicle cut, ligated, and returned to the peritoneal cavity. Returning the bladder to the peritoneal cavity he employed Peaslee's needle, and closed the abdominal wound from above downward, as is ordinarily done in this city, and twisted the silver sutures employed until the wound was closed to the opening in the bladder. Having arrived at this point he passed the needle through the abdominal wall, then through one vesical wall, then through the other, and lastly through the opposite abdominal wall, and so continued to do until the whole opening in the bladder was traversed by sutures. The sutures were then twisted, care being taken to lift the bladder well up to the surface, and the operation was completed. A Sims' sigmoid catheter was kept in the bladder, the patient removed to bed, and the after-treatment conducted upon general principles. Convalescence was regular and rapid. At the end of three months the patient went back to Canada perfectly well.

With reference to diagnosis when this complication exists, Dr. Thomas believed it to be impossible to make a correct one before the abdominal incision was made. The operator must depend upon his own quickness of perception, and upon the careful examination of suspicious tissues by sight, touch, the tenaculum, and the scalpel. If the bladder be attached to the tumor extensively and closely, diagnosis by these means will generally prove difficult; if it be attached to the abdominal wall, it will be still more difficult. After the diagnosis is made, the adherent bladder should, if possible, be separated by digital detachment; if the attachments are so strong that they cannot be broken without danger of lacerating the bladder, he recommended making an incision in the anterior wall of the organ, introducing the index finger as a guide to its outer limits, and then cutting through the adhesions. After the anterior wall of the bladder has been incised, either by accident or intentionally, it seemed to him that the plan of clamping the lips of the incision between those of the abdominal wound promised much better results than that of sewing up the opening with sutures and returning the repaired viscus to the abdominal cavity.

The paper was discussed by Drs. Kimball, Noeggerath, Engelmann, Goodell, Emmet, and Drysdale.

Dr. T. A. Reamy, of Cincinnati, then read a paper, entitled:

### A CASE OF PARTIAL INVERSION OF THE UTERUS CAUSED BY A FIBROID POLYP.

It was accompanied by a specimen. The tumor at the time of the operation was found to be attached to the fundus to the extent of two inches, and at the time of its removal it weighed one and three-fourths pound. It measured five and one-half inches in its transverse diameter, and three inches from above below. It had no pedicle; it exhibited a cup-shaped depression at the point where it was dissected from the uterine wall. The patient was an unmarried lady, aged twenty-four years, who menstruated irregularly during the first six months of her menstrual life, but subsequently her periods were regular up to the age of twenty-one. From that time menstruation became more prolonged, and she suffered occasionally from metrorrhagia, and sometimes the vaginal discharge was irritating in character. On several occasions vaginal hemorrhage was profuse. One peculiarity in the case was, that Dr. Reamy was unable to obtain any evidence by physical exploration of cupping of the fundus. He supposed that he had detected the existence of a pedicle, however, before the operation, but at the time of the operation what was supposed to be a pedicle was demonstrated to be only an inverted portion of the uterus. The case was interesting as illustrating the difficulty of diagnosis, notwithstanding all the improved methods, and showed that there is danger of making the mistake of regarding an inverted portion of the uterus as the pedicle of a polypus. In the light of the present case he should hereafter be exceedingly

solicitous with regard to diagnosis, and in the least doubtful cases he should hesitate, and at once quarter the tumor with the scissors and clear up this doubtful point.

Dr. Barker, of New York, referred to a case which had a peculiar feature, namely, that when the tumor was delivered and the pedicle cut, just as the last part of the incision was completed, the uterus, which had been inverted by the operation, immediately replaced itself with an audible noise.

Dr. Goodell, of Philadelphia, thought that in these cases it was safer to proceed by drawing the tumor fully into view, for then the operator might be able to find a line of demarcation. He then referred to a case in which he removed a polypus about the size of a fetal head. It was necessary to make extensive lateral incisions into the perineum, but, despite that, it was torn extensively. When the tumor was delivered he found a line of demarcation, and in that instance the capsule was incised, and the tumor enucleated without the slightest difficulty. The perineum was closed with sutures, and the patient made a good recovery.

Dr. Byrne, of Brooklyn, had seen two cases precisely similar to that reported by Dr. Reamy; and he remarked that if there was any means of disposing of such masses more dangerous than another, it was the écraseur. He should prefer to dissect such masses piecemeal by any means rather than apply the chain. When there is any doubt as to whether there is a partial inversion of the fundus of the uterus, an important point is to return the mass before any tightening is made. With regard to the means employed for removing these masses, he had used only a heated wire.

The paper was also further discussed by Drs. Taylor and Emmet, Sims, Lusk, and Putnam-Jacobi, of New York. The discussion was closed by Dr. Reamy, who directed special attention to the fact that the partial inversion in his case could not have become complete, because of the inability of the tumor to escape through the rigid vulvar opening.

---

Friday—Third Day—Afternoon Session.

The society was called to order at 3 P.M. by Dr. Campbell.

Dr. A. H. Smith, of Philadelphia, then read a paper on

### Axis Traction of the Obstetric Forceps.

How shall instrumental delivery be effected as nearly as possible according to the process of nature, with the least strain upon the tissues of the mother and the child, and with the least expenditure of strength upon the part of the operator? To accomplish this most effectually, the force employed must be exerted contrary to the line of resistance, therefore necessarily in the line of the pelvic axis. The mathematical argument of the question the author of the paper did not enter upon, because that had been so thoroughly studied and presented by other writers. For himself, he had settled the question that axis traction was the only proper method by which a child could be delivered with forceps, and he raised the question whether the ordinary forceps, well constructed, were not sufficient to do all that was required in this direction. There was no doubt but what the old teachers and writers on obstetrics recognized in their every day experience the necessity for axis traction, but none of them had given any suggestion in regard to the matter in their works. The first writer who had called attention to the subject was Ojeander, of Gottingen, in 1799, who speaks of it as being necessary, and describes the method by which it can be accomplished. Dr. Smith then proceeded to give the views of this old author, and gave a detailed description of his method. It was essential that pressure should be made downward upon the lock of the instrument in a line parallel with the axis of the superior strait, or the strait of that portion of the pelvis in which the head of the child is engaged, and at the same time make upward leverage with the other hand on the handles of the forceps. This was the principle enunciated by Ojeander, and it was that which Dr. Smith believed all obstetricians would adopt sooner or later. The same principle was recognized by Naegele in 1843, when he recommended the use of a fillet placed over the lock of the instrument, by which traction could be made downward. Dr. Smith spoke particularly of Tarnier's forceps, and remarked that he regarded them as exceedingly dangerous and complicated, although he had not used them upon the living subject. Dr. Smith then asked the question, Can axis traction be effected by any manœuvre with ordinary forceps? His answer was emphatically in the affirmative; and he said that he stood the humble advocate of the principle enunciated by Ojeander, and which could be formulated as follows: Place the palmar surface of one hand upon the lock, and the index finger of the same hand in contact with the head of the child; then make downward pressure with the same hand firmly fixed upon the lock, exactly in a line parallel with the plane of the axis, while, with the other hand upon the handle of the instrument, the pressure downward is antagonized by lifting upward, producing thereby a leverage. To accomplish delivery according to the principle enunciated, it is his practice to use the simplest ordinary obstetric forceps; and that which he specially recommended as best of all was the Davis forceps. He then illustrated upon the manikin with the long Davis forceps how a child could be delivered from the superior strait, and also how a child could be delivered with one hand with the Davis short forceps in accordance with the same principle, when only a slight degree of axis traction was necessary.

Dr. William T. Lusk, of New York, gave a demonstration of the use of Tarnier's forceps, and advocated their special applicability to cases in which the head of the child is at the brim of a moderately contracted pelvis, and the instrument must be used within the cavity of the uterus.

Dr. Barker, of New York, spoke of the value of Tarnier's forceps in a certain class of cases where the head is high up and prompt delivery is demanded.

Dr. Howard, of Baltimore, cited cases in which he had effected delivery with the greatest facility with Tarnier's forceps after other instruments had been used unsuccessfully.

Dr. Ellwood Wilson, of Philadelphia, was glad to hear that the Tarnier forceps should be discarded in a large class of cases—that is when the head is low down in the pelvis. Theoretically he did not regard them as in any way superior to the more ordinary instruments.

Dr. Thomas, of New York, indorsed the use of the Tarnier forceps for a certain class of cases, and regarded the instrument as an advance in the way of mechanical appliances for the relief of human suffering.

Dr. Taylor, of New York, thought that, if the instrument was guided by an intelligent hand, it mattered but little what form was employed.

Dr. Reamy, of Cincinnati, had used the Tarnier forceps, and yet was not willing to fully accept them. He thought that their use was admissible even less frequently than stated by Dr. Lusk.

The discussion was closed by Dr. Smith, who said that his paper was not an attack upon Tarnier's forceps, but one in which he simply attempted to prove that the old forceps were sufficient to do all that was required.

# Correspondence.

## A WORD FOR DR. BEARD.

To the Editor of The Medical Record.

Sir: I have read with much surprise and regret the rather intemperate letter of Dr. J. Crichton Browne in the *British Medical Journal* of August 27th, relative to the experiments in hypnotism by Dr. Beard before a medical audience at the Waterloo Hotel in London. The arguments used by the writer would apply equally well to vaccination, and, indeed, were so applied a hundred years ago to Jenner, when he was endeavoring to induce the medical profession of England to take more interest in the investigations he was conducting. Admitting that Dr. Beard failed in every one of his illustrations, the fact of such failure is no valid evidence against the truths which Dr. Beard has done so much to establish, and certainly gives no warrant for the insulting questions which Dr. Browne addresses to him at the conclusion of his letter. As these questions show the animus of Dr. Browne, and as they, at the same time, exhibit his absolute ignorance of the essential points of the inquiry, I propose, with your permission, to take upon myself the office of answering them.

And I may, in the outset, remind you and your readers that probably no one in this country has had more frequent occasion than have I, to differ with Dr. Beard. I have come in antagonism with him on so many different points, that I am quite sure I know with accuracy his character and mental methods. I have criticised him in debate and in written communications, and I have endeavored to deal him as effective blows as I could whenever I have had to controvert his views. He has always had the good sense to take my animadversions with kindness and in true scientific spirit, and I have never observed the slightest tendency in him to act dishonestly, unfairly, or in any other way dishonorably or in a manner unbecoming a gentleman and a scholar. I am no especial friend of his, but while there has been no intimacy between us, our personal relations have always been pleasant. I have not seen him for several months, and have had no written or other communication with him relative to the present matter. He has not the slightest idea that I am writing this letter. We have never worked together in hypnotism or in any other subject.

If he were at home I should probably leave him to defend himself, as he is well able to do, and as he certainly will in his own way, but I have been so greatly shocked by the unjust imputations that Dr. Browne has cast upon him, that I address you under a keen sense of justice to a gentleman who has been treated with gross unfairness where he had a right to expect kindness and consideration.

With this explanation of my relations with Dr. Beard, which I should not think it necessary to make if this letter were to be read wholly in this country, I proceed to take up Dr. Browne's questions *seriatim*.

*First.*—"Did he [Dr. Beard] know when he brought his 'trained subject' to this country that he was passing under an assumed name, and did he withhold the knowledge of that fact from several parties of medical men who had witnessed his experiments, and from the meeting of the 6th inst., until it was elicited by the rigorous cross-examination to which the 'trained subject' was submitted."

It was not of the slightest consequence whether the subject was or was not passing under an assumed name; neither was it of any moment, one way or the other, whether or not Dr. Beard knew the fact. If the subject was passing under any other name than his real one, and confided the fact to Dr. Beard, it was manifestly Dr. Beard's duty to keep the secret. Dr. Browne might as well find fault with Lord Lytton for writing under the assumed name of Owen Meredith, or with the many other literary persons of both sexes who have given their lucubrations to the world under other names than their own; or with those royal personages who, desiring to escape irksome ceremonies or attentions, drop, when they travel, their real names, and assume others less likely to attract notice.

As a matter affecting the scientific aspects of the case, the name of the individual subjected to experiment cannot, in my opinion, be of the least importance; neither can any reason the man may have had for concealing his real cognomen be a factor of the slightest consequence. He may have been modest, and desirous of escaping notoriety; he may have had "expectations" from an uncle who did not believe in hypnotism; he may have stolen a sheep, and have been afraid of the myrmidons of the law. There may be some occult influence in a man's name when he comes up for hypnotic experiments, and it may be necessary that he should have the one his sponsors in baptism gave him; but, with all due deference to Dr. Browne, I am not aware that such is really the fact. So far as I have been able to ascertain, Smith may call himself Jones without disturbing the conditions requisite in experimental hypnotism.

*Second.*—"Did he know that the trained subject had taken part in mesmeric and spiritualistic performances previously to his coming under his cognizance; and, if so, did he withhold the knowledge of that fact from the parties of medical men who were invited to witness his hypnotic achievements?"

Again, from what is perhaps a natural obtuseness, I fail to see what possible bearing this question has on the matter, even admitting that the "trained subject" had at some former period of his life "taken part in mesmeric and spiritualistic performances." It might as well be asked if he had ever belonged to a circus, or whether he was a Mormon or not.

As a matter of fact, however, I am very positive that the "trained subject" never did take "part in mesmeric and spiritualistic performances." He had been one of those called up from the audience on several occasions by a Mr. Carpenter, who was last winter giving public exhibitions of hypnotism. I have several times had him at my house for purposes of study, and once took him before the medical class of the University of New York as a subject

for the elucidation of some of the phenomena of hypnotism. As to mesmerism or spiritualism, he has never, I am quite sure, had anything to do with them. Dr. Beard knew that he had appeared in public, and he very naturally thought it a matter of no consequence one way or the other. Dr. Browne does not distinctly intimate by his word "withhold" that Dr. Beard wilfully falsified about the matter; but if he does mean to be so understood, I can only say that it will require much more than his insinuation to make those who know Dr. Beard believe that he is a liar.

*Third.*—"Had he never, till the exposure of the 6th instant took place, had any suspicion that any part of his 'trained subject's' performance was a mere piece of acting?"

This is a distinct intimation of fraud on Dr. Beard's part. If his subject was a mere actor, and Dr. Beard knew it, then undoubtedly he was guilty of deceit in attempting to palm him off as a veritable hypnotized person. But if Dr. Browne has any right to ask such a question, he can only base that right on actual knowledge of Dr. Beard's lack of credibility. If he has no such right, it is a grievous wrong for him to ask this question. I remember once, when a boy, hearing a rather unscrupulous lawyer undertake to break by cross-examination the force of some very damaging evidence which had been given against his client. The witness was a timid young man, but had given his testimony in chief clearly, and with evident regard for the sanctity of his oath. What, therefore, was his surprise to hear himself addressed: "Well, sir, please to remember that you are under oath. Now, sir, tell the court and the jury whether or not you were once in jail for stealing a watch." The young man arose, looked at the judge helplessly, and then burst into tears. The judge spoke to him kindly, very soon ascertained that there was no ground for the question, and then he administered a sharp rebuke to the limb of the law. The object of this latter individual was, however, very apparent. It was to confuse the witness and to prejudice the jury against him, and it looks to me very much as though Dr. Browne was actuated by a similar motive.

*Fourth.*—"Did he inform his audience on the 6th instant that he had exhibited his experiments before the Academy of Medical Science at New York, and was that statement promptly and emphatically contradicted by Dr. Adams, the Secretary of the Academy, who happened to be present?"

I think I may venture to answer the first part of this question emphatically in the negative, for the simple reason that there is no such society in New York as the "Academy of Medical Science." There is an "Academy of Medicine," and an "Academy of Sciences," and the meetings of the latter body are held in the hall belonging to the former, and Dr. Beard did exhibit his experiments before the "Academy of Sciences," in the hall of the "Academy of Medicine." Dr. Adams will certainly not contradict this statement. Dr. Browne is scarcely more exact in his knowledge of New York societies than some of his countrymen are of American geography.

*Fifth.*—"Was he invited, after the failure of his 'trained subject' to secure confidence, to join the meeting in expressing satisfaction that a gross case of deception had been exposed, and did he refrain from making any response to that appeal?"

If he was so invited, and declined to accede to the request, the idea that would most readily occur to non-prejudiced persons would be that he differed with Dr. Browne and the other gentlemen present relative to the conclusions at which they had arrived. Dr. Beard knows more about the subject of hypnotism than all the fifty medical gentlemen at the meeting put together. He has studied it in all its relations; has performed a great many original experiments to elucidate its features; has constantly been on guard to avoid being imposed upon; has written and spoken upon the subject dozens of times; and has strong convictions in regard to it, which spring, not from what others have said, but from what he has found out for himself. To expect him, therefore, even admitting that his "trained subject" failed, to renounce, on the spur of the moment, views that had been formed from the investigations of many years, was, I humbly submit, slightly preposterous, and his refusal to do so is the best possible evidence of his honesty and sincerity. For nothing would have been easier for him than to have made a scapegoat of his fraudulent "trained subject," and so have escaped with the commendations of the whole meeting on his artlessness and devotion to the true interests of science. Whether the "trained subject" was or was not a fraud at the Waterloo Hotel meeting, it is very evident that Dr. Beard believed in his integrity; otherwise he would have consulted his own interest by joining Dr. Browne and his colleagues in denouncing the cheat of which he himself was the chief subject.

As Dr. Beard very properly says in the London *Times*, the moral character of the hypnotized individual is no factor in the case. All that is requisite is a man or woman of some kind. The person whom Dr. Beard took with him has stood many tests which the most intensely conscientious and moral man would not have been able to stand had he been a fraud. I have myself subjected him to such tests, and I have cut, and pricked, and burnt, and faradized others while they were in the hypnoptic state, and they have not winced. I have seen the man in whom Dr. Beard, before the Academy of Sciences, slowly burnt a deep hole with a red-hot iron, and whose hand was sore from an open ulcer for over a month. It is no wonder, therefore, that these people shrink from such experiments, even though they suffer no pain at the time they are performed.

It is quite evident to me that Dr. Browne went to the meeting with preconceived views, to which he was determined to adhere, and with an overpowering intention to bring Dr. Beard to grief. For the time being he appears to have succeeded, but his triumph will not be of long duration. History repeats itself. Not many years ago Mr. Braid, of Manchester, discovered the true nature of what was called mesmerism. He wrote an elaborate paper on the subject, which he wished to read before the British Medical Association. Permission, however, was refused, and Mr. Braid was denounced as being no better than he should be. He lives, however, to see his views accepted by all intelligent inquirers into the subject. Doubtless Dr. Beard will enjoy a like experience, except, perhaps, in some few minor points, which greater study on his part will elucidate. At any rate, he will quite certainly not be overwhelmed by such attacks as that of Dr. Browne.

WILLIAM A. HAMMOND.

AN OUTBREAK OF SPLENIC FEVER has occurred recently among the cattle at Lincoln, Nebraska, according to our correspondent, Dr. W. A. Thomas, of that place.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October 2, 1881, to October 8, 1881.*

MURRAY, ROBERT, Colonel and Surgeon, Medical Director Mil. Div. of the Missouri. Granted leave of absence for two months. S. O. 100, Mil. Div. of the Missouri, October 5, 1881.

BYRNE, C. C., Major and Surgeon. To proceed from Wilcox to Camp Thomas, A. T., and report to the commanding officer for duty in the field. Field-orders No. 4, Dept. of Arizona, September 9, 1881.

CLEARY, P. J. A., Capt. and Asst. Surgeon. Granted leave of absence for six months on surgeon's certificate of disability, with permission to apply for six months' extension, if necessary. S. O. 224, A. G. O., October 4, 1881.

KOERPER, E. A., Capt. and Asst. Surgeon. Now awaiting orders at Philadelphia, Pa., to report in person to the commanding general Dept. of the East for assignment to duty. S. O. 222, A. G. O., October 1, 1881.

KING, WM. H., Capt. and Asst. Surgeon. To proceed without delay to Fort Trumbull, Conn., and report to the commanding officer for temporary duty. S. O. 176, Dept. of the East, October 3, 1881.

O'REILLY, R. M., Capt. and Asst. Surgeon. Granted leave of absence for six months from December 1, 1881, on surgeon's certificate of disability. S. O. 225, A. G. O., October 5, 1881.

MAUS, L. M., Capt. and Asst. Surgeon. Granted leave of absence for four months. S. O. 222, C. S., A. G. O.

APPEL, D. M., Capt. and Asst. Surgeon. Relieved from duty at Fort Supply, I. T., and assigned to duty at Fort Elliot, Texas. S. O. 201, Dept. of Missouri, October 4, 1881.

STRONG, N., 1st Lieut. and Asst. Surgeon. When relieved by Asst. Surgeon Shannon from duty at Ft. Thornburgh, U. T., assigned to temporary duty with troops repairing road between Park City and Fort Thornburgh, U. T. S. O. 102, Dept. of the Platte, October 4, 1881.

## Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending October 8, 1881.

| Week Ending | Typhus Fever. | Typhoid Fever. | Scarlet Fever. | Cerebro spinal Meningitis. | Measles. | Diphtheria. | Small-pox. | Yellow Fever. |
|---|---|---|---|---|---|---|---|---|
| Oct. 1, 1881. | 1 | 30 | 76 | 7 | 9 | 90 | 8 | 0 |

PRESIDENT GARFIELD'S TEMPERATURE.—On page 398, Dr. Bliss's report, under date of September 19th, the temperature of the President was 100.8° F., instead of 108.8° as misprinted.

THE CLIMAX OF THE ANTISEPTIC SYSTEM.—At the most recent duel the adversaries were about to cross swords, when a voice called upon them to stop. It was that of the surgeon in attendance, who, imbued with modern ideas, took from his pocket a bottle of carbolic acid (1 to 20) and carefully moistened the ends of the blades therewith. He then exclaimed, with the air of a man who had done his duty, "Proceed now, gentlemen, you may kill each other, but at all events you are safe from purulent infection." —*Lyon Medical.*

THE DEATH OF DR. WILLIAM WARREN GREENE, of Portland, who was a delegate to the International Medical Congress, occurred at sea, while on his return voyage. He was a leading physician of Portland, confessedly one of the ablest surgeons in Maine, and one of the most skilful in the country. He was a graduate of the Ann Arbor Medical College, and for a time was connected with the Long Island College. Since 1866 he was at Bowdoin College, where his clinic gave him fame very early. He was President of the Maine Medical Association last year. In age he was a little over fifty years.

THE DEFLECTION OF THE BULLET.—A correspondent writes that the remarkable deflection of the bullet in the body of the late President is explicable on the theory that he was inclining his body to the left, as it is very likely he was doing, when struck at the second fire. A strong inclination of the body toward the left would be attended with a convexity of the spinal column toward the right, and a rotation of the bodies of the vertebræ still further toward the right, which may readily be believed to have brought the lateral face of the body of the first lumbar vertebra nearly at right angles with the direction of the bullet as it entered the body.

A NATIONAL CATTLE COMMISSION.—At a meeting of the American Institute Farmers' Club, in this city, on September 13th, Dr. A. H. Heath, presiding, the following resolutions were adopted:

*Resolved*, That in our judgment the appointment of a permanent United States commission to protect these most valuable manure-producing animals should be made. We therefore urge on the Commissioner of Agriculture, and upon every member of Congress, the necessity of a law to furnish the protection needed, with ample means and powers to enhance so vital an element of our national prosperity.

THE ANNUAL REPORT OF THE SUPERVISING SURGEON-GENERAL OF THE MARINE HOSPITAL SERVICE, for the fiscal year ended June 30th, shows that during the year 32,610 sailors received relief at the different hospitals and dispensaries, and 17 incurables received transportation to their homes. An increase in the number of patients is shown over last year of 7,750. In addition to the relief furnished, 305 seamen of the Revenue Marine Service have been examined preliminary to shipment, 4,384 pilots have been examined for color-blindness (of whom 116 were found color-blind), and 57 seamen were physically examined for the Light-house and Merchant Marine services. "No objection," the report says, "is now made to the examinations for color-blindness, the pilots themselves being generally convinced of its utility." The receipts for the year were $381,000 and the expenses $402,000. The expenses are a few hundred dollars less than last year, notwithstanding the fact that the number of patients has increased more than 7,000.

# Original Lectures.

## RUDOLF VIRCHOW.

AN ADDRESS, INTRODUCTORY TO THE COURSE OF LECTURES OF THE TERM, 1881–1882.*

BY A. JACOBI, M.D.,

CLINICAL PROFESSOR OF DISEASES OF CHILDREN.

*Mr. President, Gentlemen of the Faculty, Fellow-Practitioners, and Fellow-Students*—The bust exhibited here, and the portrait shown, are those of Rudolf Virchow. His name is familiar to all. His renown as a great scientist is older than probably any student in this hall, of as long duration as the life of many a practitioner of great skill and deserved reputation, and has been firmly established so long as to have accompanied the oldest of us through the best and most efficient part of our career. Him I selected for the subject of our conversation this evening. In my opinion there is nothing we can learn so much from as from the life of a great man. If that man be dead, his biography is a source of valuable instruction and admiring appreciation; if he be among the living, and known not to have spent a day of his life except in the service of science and mankind, he is deserving of being extolled to the young—and old too—as a praiseworthy example. And if he can be shown to unite with the accomplishments of a savan the traits of genius, a universality of interests, and the beauties of a manly and refined nature; and further, if it can be demonstrated that no man in old or modern time crowded more successful scientific work into one lifetime, that man ought to stand out before the eyes of the young man entering upon the study of medicine as his guiding-star, as his ideal. For an ideal it is which the young want and require. Fortunate are those who look for theirs among the best and most perfect.

Rudolf Virchow was born on October 13, 1821, in a little Pomeranian town—Schivelbein—in Northern Germany. In 1843 he graduated in medicine at the University of Berlin. In 1846 he was made prosector of the Charité Hospital, and controlled in that position the whole anatomical material of that great institution. His facilities he utilized at once in delivering courses of lectures on the subject of pathological anatomy. In 1847 he was appointed a regular lecturer in the University. In the same year, together with Reinhardt, who died in 1852, he founded his *Archiv for Pathological Anatomy and Physiology and for Clinical Medicine*, which has since completed its eighty-fifth volume.

In 1848 the Government sent him to Upper Silesia to study the typhus fever begotten by the misery and starvation of a vast population. His report was a masterpiece, containing close observations both of medical and social facts, highly valued by the profession, and, like his later book on the misery in the Spessart Mountains, by those in power and responsibility.

In 1849, together with Leubuscher, who also died young and too soon, like Reinhardt, he edited the *Medical Reform*. The ideas proclaimed by him, and his participation in the liberal tendencies of the revolutionary movement of 1848 were disliked by the Government. He was dismissed from his public positions. But the medical societies of the city were so unanimous in their efforts to retain him that he was reinstalled; *for there is, after all,* ONE *force* more powerful and influential than swords and cartridges, even in soldier-stricken Germany, viz., public opinion. Still he did not remain long in Berlin, but accepted the Chair of Pathological Anatomy in the University of Würzburg, which he held until 1856, when he returned to Berlin in the same capacity.

Before he left Würzburg, he published his "Collection of Contributions to Scientific Medicine" (Frankfort-on-the-Main, 1856). His celebrated papers on "The Movement in Favor of Unity in Scientific Medicine," first published in 1849, head the list. I shall simply mention the titles of the rest in order to recall to the older gentlemen in this audience the great revolutions in physiological and pathological knowledge which have taken place in our lifetime. There are his essays on "The Physical and Chemical Properties," the "Metamorphosis," the "Origin and the Coagulation of Fibrine," all of them written in 1845 and after. There are his celebrated papers on "White Blood-Corpuscles" and "Leukæmia," dated 1845 and after, and his five hundred pages on "Thrombosis and Embolism," "Inflammations of Blood-Vessels," and "Septic Infection," dated from 1846 to 1853; also "Contributions to Gynecology," with papers on the "Puerperal Condition" (1847); the "Formation of the Placenta" (1853); "Uterine Flexions" (1850); "Prolapse of the Uterus" (1846); and "Extra-Uterine Pregnancy" (1850–56); on the "Elimination of Uric Acid in the Fœtus and Newly Born" (1846); "Congenital Hydronephrosis" (1854); and on "Apoplexy in the Newly Born (1850); "Contributions to the Pathology of the Skull and Brain," which contain papers on the "Granular Appearance of the Walls of Cerebral Ventricles" (1846); on "Cretinism" (1851 and 1852); on the "Development of Cretinism" and "Cranial Deformities," on the "New Formation of Gray Cerebral Substance" (1851); and on "Senile Involution of Flat Bones" (1852); finally, a "Paper on Cancroids and Papillomata" (1850).

About the same time he was active with other problems. The "Collection of Treatises connected with State Medicine and Epidemiology" (Berlin, 1879), contain a number of papers written at that time. The two volumes treat in scores of different articles, written between 1848 and 1879, on subjects connected with public hygiene, reform of medicine, epidemics and endemics, statistics of morbility and mortality, hospitals, military medicine, cleaning of cities, school hygiene, criminal law, and forensic medicine.

However, when Virchow's name is mentioned, it is customary to think of him first as a great discoverer in the field of pathological anatomy.

Pathological anatomy is that part of pathology which treats of the origin, development, and nature of such changes in the solid and liquid parts of the body as constitute disease. The changes most thoroughly and profoundly studied, were, in the beginning, the gross and macroscopical, afterward the morphological ones, inclusive or exclusive of pathological chemistry, which is still younger than pathological anatomy proper. If I speak of origin, development, and nature of changes, I characterize the science as it is to-day. For neither Theophil Bonetus, who, in 1675, collected the three thousand post-mortem examinations recorded for two thou-

* Delivered in the lecture-room of the College of Physicians and Surgeons, New York, October, 3, 1881.

sand years past, nor Morgagni, in his celebrated book on "The Seats and Causes of Diseases studied Anatomically" (1761), nor Bichat (1801), with his attempts at studying the diseased tissues, nor Aloys Vetter (1803), in his "Aphorisms from Pathological Anatomy," nor the first prosector, Biermayer, of the Allgemeine Krankenhaus, in Vienna—founded by Emperor Joseph, *Saluti et Solatio*—nor his successor Wagner, considered anything but the completed changes of the organs. Wagner's successor in the place, which was founded on the 26th of June, 1812, was Carl Rokitanski.

To estimate at its full value the influence exerted by *him*, let us consider the facilities for diagnosis at those times by choosing an example from the large class of fevers. There were catarrhal fevers, with the symptoms of a slight catarrh prevailing; when muscles or joints ached, the fever was catarrho-rheumatic or rheumatic; when the gastric symptoms prevailed, it was gastro-catarrhal or gastro-rheumatic; with a yellow tongue and pain in the right epigastrium, it was bilious, or gastro-bilious, or bilious-rheumatic; with prevailing headache or delirium, it was gastric-nervous, or bilio-nervous-rheumatic. There was no end of complication of terms, just as little as there can be an end to the complication of symptoms. That was a time in which nothing better could be done. Most diseases were estimated from the nature of either the subjective or the most superficial objective symptoms of the pulse, the tongue, etc. It was exactly the period in which even the Hahnemannian system, school, sect, was just as easy of existence as any other system, school, sect, or self-styled scientific silliness. Rokitanski's great function was to find, as Andral had done shortly before him—to proclaim louder and more effectually than Andral ever succeeded in doing, that disease meant a change of structure and not of sensations and symptoms, and to point out, as Virchow happily expresses it, "a number of natural and easily recognizable types of disease." If I call your attention, by a simple example, to typhoid fever, which Rokitanski installed as an anatomical entity, instead of the nervous, and bilio-nervous, and gastric, and what-not fevers, you have at once an instance of the blessing conveyed by one great man on both the anatomist and the physician. He proved that the most various symptoms can depend on the very same or similar anatomical changes, and could prove that sometimes the same or similar symptoms might depend on different conditions. Thus, the similarity of many symptoms in typhoid fever and acute tuberculosis gave rise to many errors, many studies, until Skoda's skill and genius solved the grave problem of differential diagnosis. To treat of Rokitanski's merits fully is not appropriate to-night. His place in the history of medicine is secure. But still he will not appear—nobody will—as the last and unimpeachable judge in all matters anatomical and histological. On the contrary, his labors, as laid down in the first volume of his pathological anatomy, were undertaken, and in part finished, during the time in which Schwann first found all animal tissue to consist of cells. Thus, the histology even in his *second* volume (1846) is of inferior character. This is the first defect. His second error and that of his school is the assumption of humoral pathology in a somewhat new shape. The mixture (crasis) of the blood, engendered by the chemical examination of the blood by French authors such as Andral and Gavarret, was considered the main cause of many general, constitutional, or feverish diseases. The third great mistake of Rokitanski was this, that he felt convinced, and acted upon the conviction, that *his* special branch of pathology contained everything worth knowing in medicine. Remember, however, *he* lived in the dissecting-room; remember that from November 1, 1817, to October 8, 1878, seventy thousand and eighty-seven post-mortem examinations were recorded in Vienna. If you do, you will understand, and, though you deplore it, pardon the one-sidedness with which he considered that his efforts were everything required, not only for the theory, but for the practice of medicine. He found organs destroyed, or changed to such an extent that life was incompatible with that destruction or those changes. Where was the remedy which could have restored to health the organ which had produced death. *Non possumus.* Impossible. Thus he became the intellectual head of the so-called school of Vienna, which, while it increased rapidly the anatomical knowledge and differential diagnosis of the conditions of diseased organs, threw up its hands in despair when the living patient clamored for relief and recovery.

Thus, the three great defects or errors of Rokitanski and his school were: ignorance and regardlessness of histology, the clinging to humoral pathology, and the therapeutical nihilism originating in Vienna and infecting a large portion of the practitioners of the world. Let us now turn to Virchow to discover how he dealt with these defects, errors, and difficulties.

Before and about the time when Rokitanski worked and wrote, and Virchow prepared to commence his career, medical science in Germany was by no means independent and self governing. There was no country in Europe in which observation and regard for facts, and facts only, was less esteemed than in Germany. England had enjoyed a predilection for pathological anatomy since John Hunter; Carswell had studied the elementary forms of morbid processes in his pathological anatomy (1833); physiologists such as Bell and Marshall Hall had added to the stock of positive knowledge; great physicians, such as Bright, Abercrombie, Hope, Williams, and afterward Stokes, enriched special fields of pathology. France lived through its most brilliant medical career. Never before, or after, have more illustrious, sober, and painstaking men worked in the same field with more success than those who sustained French medicine up to 1840 in its high rank. Bichat, Bayle, Dupuytren, Laennec, Cruveilhier, Rostan, Chomel, Gendrin, Bretonneau, Andral, Louis, Billard, Piorry, Magendie, and many others, placed French medical science far above the level of any other country. Meanwhile, German medicine was controlled by what was called philosophy, and mainly by the so-called philosophy of Nature. The only great philosopher of the end of the eighteenth century was no longer appreciated or understood. Immanuel Kant, with his clear intellect, his unbiassed judgment, his mathematical training and scientific method, was forgotten or misinterpreted. One hundred years ago this year, his "Criticism of Pure Reason" made its appearance. This very year the orthodox churches of all sorts of denominations have claimed this scion of natural facts, of mathematical problems, this personification of pure reason and unfettered logic, as their own, in this very city of ours. We need not wonder, then, that neither Fichte, nor Schelling, nor Hegel, nor even Hegel's greatest pupil, Feuerbach, followed the road opened by the unsophisticated, shrewd, far-seeing,

untrammelled genius of Kant. Under the influence of the German philosophy of that whole period, after Kant, which has been so unintelligible that it was called profound, and so abstruse that it has procured for the whole German nation the title of the people of thinkers, everything in medicine not accepted because it was old and traditional was a matter of speculation *a priori* only. The bases of speculation were premises construed by reasoning not founded on facts; by theories not built on experience, far less on experimentation. Both facts and experimentation were claimed by Virchow as the only admissible foundations of scientific medicine, no matter how long it would take to collect them or to establish it. At the same time he was perfectly well aware that the literature of the last two thousand years contained a great many available points; nobody ever was more honest in collecting material and giving credit. Every one of his books, orations, speeches, essays, lectures, teems with literature carefully collected and critically judged, and proves his appreciation of the necessity of historical studies. As the organism of the human body cannot be understood without the knowledge of its gradual development, thus the present condition of medicine, or the present condition of a doctrine, cannot be appreciated without the history of the labors spent on its gradual completion, no matter whether it was obtained by uniform progress, or, what happens much more frequently, by alternations of progress and retarding relapses. For the history of human progress is, in part, the history of errors.

The young student cannot possibly imagine, without historical studies, the condition of our knowledge as late as thirty or forty years ago. Many of the distinguished men here assembled—many of your celebrated teachers on whose lips hang your eager eyes, and whose every word is cautiously remembered by willing ears, lived and studied in a time when capillaries were not known to be true vessels with a wall of their own, when the distribution of the peripheric nerves was not even believed by the most poetical imaginations, when the action of organic muscular fibres, with its universal influence on the function of every organ, was not deemed a possibility, and trophic nerves were not even dreamed of.

The first opposition to the influence on medicine of the so-called philosophy of nature, was made by "rational" medicine and the "physiological" school of medicine. It was formed by such learned and ingenious men as Wunderlich and Roser; it controlled the minds and influenced the action of many good men in the profession a number of years. At that time, and long after, pathology was acknowledged as only a part of physiology. At all events it had no independence of its own. Pathology was an appendage of the natural sciences then recognized. *The emancipation of pathology*, its rise into the number of independent sciences, with, *in its turn*, its fertilization of anatomy and physiology, dates from April, 1847, when Virchow wrote on the *standpoints in scientific medicine*, in the first volume of the *Archiv for Pathological Anatomy and Physiology and for Clinical Medicine*. At that time he wrote as follows:

"We ought not to deceive ourselves or each other in regard to the present condition of medical science. Unmistakably, medical men are sick of the large number of new hypothetical systems which are thrown aside as rubbish only to be replaced by similar ones. We shall soon perceive that observation and experiments only have a permanent value. Then, not as the outgrowth of personal *enthusiasm*, but as the result *of the labors of many close investigators*, pathological physiology will find its sphere. It will prove the fortress of scientific medicine, the outworks of which are pathological anatomy and clinical research."

Five years afterward he could say: "The scientific method of medical research is firmly established. It is not my merit to have discovered it. Without me it would have been found, and the new trail would have been followed. But I trust that the battle against the existing mixture of arbitrary rationalism and gross empiricism, fought by the *Archiv*, in which I aided by the introduction of genetic investigation, must have contributed much in procuring new aims for pathology."

You remember that, but little more than forty years ago, Schleiden discovered the cell to be the elementary basis of the vegetable tissue. Schwann recognized the same element as the foundation of the structure of all animal tissues. A long series of observations and experiments convinced Virchow of the continuous propagation and proliferation of cells within the individual. After five years of hesitation he published the first preparation for, or introduction to, his cellular pathology, in the fourth volume of his *Archiv*, and another contribution to the same, three years afterward, in the eighth volume.

He proved, and all our experience proves, that life requires a special formation to manifest itself, and certain conglomerates of substance. These conglomerates are the cells and their compounds. Like the individual in its totality, the cell in its turn is the physical body with which the action of mechanical substance is connected, and within which the latter can retain its functions which alone justify the name of "life." In the normal state of this conglomerate it is mechanical substance which acts, and acts only on chemical and physical principles.

The pathological process within the elements, according to cellular pathology, is as follows: a living cell is acted upon by something outside. The latter works a mechanical or chemical change in the cell. This mechanical or chemical change is disorder or disease. If an action or reaction take place in the cell through that cause, the change is called irritation, the cause irritant. If no reaction take place, there is a mere lesion, or perhaps a paralysis. The same cause may act as either an irritant or a simple lesion, or be a source of paralysis. The difference of the results depends on a difference in the condition of different cells. This difference in the condition of the cell is, or rather forms, its predisposition.

Cellular pathology was intended to demonstrate the cellular nature of all vital processes, both the physiological and pathological. Thus, in contradistinction to the humoral and "solidar" (or neuristic) theories handed down from almost prehistoric times, the unity of life in everything organic was claimed as a demonstrable fact, and the minute mechanics and chemistry of the cell were placed in victorious opposition to the course of explanations based on the mechanics and chemistry of the compound mass. With the improved instruments, and by means of the newly established principle, "all medicine got nearer the natural processes by at least three hundred times" (Virchow).

*All medicine;* for it is a peculiarity in all of Virchow's researches and conclusions, that none is without its immediate results on the theory and practice of medicine, even on diagnosis.

Diagnostic powers have increased with the growth of positive knowledge. Diseases become recognized as local anomalies in the same degree that the old humoral pathology, first objected to by Vesal and Paracelsus, was finally undermined in its position as the general explainer of physical disorders. One hundred years ago the diagnosis of most local diseases was a very imperfect one. A fever with dyspnœa, with cough or without it, was a thoracic fever—a pulmonary fever. When Morgagni had published his "Seat and Causes of Diseases," and Laennec and Dupuytren had developed more proficient means of diagnosis, the disease was sought for and found in organs—even in parts of organs. A pleurisy was diagnosed from a pneumonia, a pneumonia of the right from that of the left side, of the upper from that of the lower lobes. Bichat, though he could not prove it, yet insisted even upon the necessity of diagnosing the diseases of the several constituent tissues.

Virchow's cellular pathology is claimed by him as the consistent execution of the principles and postulates of his predecessors. The localization of disease is taken as a necessity. It is looked for in the smallest composing elements—the cells, for there is no organ but consists of cells or cell-production. Blastoderma, protoplasma, are not characterized as something independent, as organisms by themselves, no matter whether they be considered to be the changed condition from the blood, as the older writers would have it, or the shapeless, amorphous mass of the recent authors. The smallest organism we know of, and which has an independent action and a life of its own, changing under the influence of external irritants, is the cell. To fix the disease in a cell, or a group of cells, is the finest localization possible. As a rule, we have to deal with a group of cells, like the chemist, who works with and on a group of atoms.

But not only does the practitioner enjoy the benefit of a diagnosis and prognosis based upon the knowledge of local organic alterations, but his therapeutics also have undergone important changes. They, again, are mostly due to more correct observations, and mainly to the experimental method which has been generally adopted these ten or fifteen years, in the study of the effects of medicines on the animal system or organs or tissues. Therapeutics have become more and more local. The hypodermic method has taught us that the local effect of a narcotic is so much more distinct when the remedy is applied to the affected part. Strychnia, injected into a paralyzed limb, a deficient sphincter ani, or near an anæmic amblyopic retina, is much more powerful than when given internally. Relations between certain organs and certain remedies have been discovered. Quinine has been found to affect white blood-corpuscles and blood-vessel nerves; ergotin has its specific action on unstriped muscular fibres; atropia on the intestinal ganglia and on the iris; eserine, calabar are justly credited with local effects. We have remedies with specific effects on the muscle, such as salicylic acid; on the nerves, on the brain or spinal cord; we use the faradic and continuous currents for local purposes; influence local changes, pains, anomalous functions by cold, heat, moisture, contra-irritants; even remedies known for their general effects alone are used for the purpose of reaching local changes. For not only is mercurial plaster used for the purpose of dissolving local indurations, mercury is given internally for the purpose of influencing local gummata; iodine in order to remove local periosteal swellings, or chronic local adenitis. By becoming experimental, therapeutics have become sound, not only for the benefit and in the interest of diseases, but also of surgical interferences. These have never been rendered so safe and innocuous by all the accumulated experience of justly celebrated operators, of justly condemned wars, as by the theoretical reasoning of a living English surgeon, whose name is on the blessing lips of every modern physician.

But cellular pathology does not claim to be a *system* which contains everything, *but a principle*. Thus far, every new discovery of pathological facts has found a ready explanation by it and its methods. The changes worked in and by white blood-cells, the transmutation of epithelial cells into benign results or malignant growths, the influences, real or imaginary, worked by bacteria, have but strengthened its plausibility. If there be a pathological entity, this entity is the cells in a state of disease. Despite the multifariousness of the vital processes in different organs, life is—no matter whether the cell-group, the organ, the individual, well or sick, are concerned—one and the same, and depending on the same and uniform action of the independent cell.*

The three volumes on *morbid tumors*, published between 1863 and 1867, are a work which might have filled the lifetime of a great student and thorough pathologist, and perpetuated his name in the annals of medicine. Never before was sarcoma treated of so extensively and monographically. Never before was the whole literature of the subject searched with so much knowledge and conscientiousness. The etiology, development, and prognosis of morbid tumors were at last intelligibly discussed on the principles of cellular pathology, while even therapeutics were not neglected. The chapters on scrofulosis, tuberculosis, and syphilis, though the subjects were treated of in many, perhaps too many publications previously, exhibit new researches, new results on every page. The congenital deformities are always described in relation to the embryonic development of the parts, partly as arrests of development, partly as the results of inflammatory action. And not the least beauty of the great work is the fact that the material belonging to medicine and surgery, superficial and deep-seated organs, ophthalmology, dermatology, and gynæcology, is treated of under common and uniform points of view. Thus, as Virchow has proclaimed the unity of life under the most manifold manifestations, he facilitates the knowledge that, after all, the specializing tendencies of modern medicine, natural and necessary though they be to a certain extent, admit of correction and limitation.

The "Investigations on the Development of the Basis Cranii in its Healthy and Morbid Condition, and its Influence on the Shape of the Skull, the Formation of the Face and the Structure of the Brain" (Berlin, 1857), are, as it were, a continuation of the essays alluded to among the contents of the "Collection of Treatises." They have been fruitful for anatomy, psychology, and pathology. The two works have yielded the anatomical basis of my own paper on the pathological and diagnostic importance of the premature closure of the cranial sutures and fontanel (1858 and 1859) and of many more important additions to the literature of science. For himself, these studies have been of the greatest importance also. On the

* See Virchow on the Essence and Causes of Disease, in his Archiv vol. lxxix.

base created by him, his main predecessors in this field being Leuret and Gratiolet, and Huschke, he has merged into his anthropological studies, foremost among which is his book on "Some Cranial Peculiarities of Lower Human Races" (1875), and "Contributions to the Physical Anthropology of the Germans" (1876). Before these publications, however, saw the light, his cranial studies led him into palæontology and archæology. From the beginning of the existence of the Anthropological and Archæological Society of Germany, he was a member—in the second year its president. Without being able to follow him in all these studies, I lay stress only on the fact that they are by no means adverse or foreign to strictly anatomical and medical studies. The connecting link is sufficiently clear, though the literary notes I have given must unfortunately be but too short. His paper on prehistoric tombs, and many others, in part published in an anthropological journal, prove at the same time his varied interests and his mental powers, enabling him to combine such a variety of studies and occupations.

Still, his main labors have been spent on pathology and subjects connected with pathological anatomy. His papers on thrombosis and embolism alone would have immortalized him. They acted like a new revelation, by which a host of pathological occurrences and processes, formerly not understood, became intelligible.

The number of his other contributions to pathology is large. I remind you of his investigations on caseous and tubercular degeneration, and on diphtheria. What our Dr. Billings lately said in his London discourse is certainly true. For pathology we do look to Germany—he might well have said, to Virchow and his pupils. Never can too much credit be given to him—never ought he to have been compelled to express himself as follows:

"For years," he said lately, "I became accustomed to the fact that others utilize my labors. I complained of that in 1856, and have more reason now. Many pupils who learned the new results of my researches in my lectures have not always remained conscious of the source of their knowledge, and thus they have not always been in a condition to give me due credit in their publications. I do not propose to attribute that to ill-will in every case. We all live in motion and turmoil, and are the recipients of much which, without recalling the giver, we consider our own. Whoever has gathered around himself many pupils through many years, must expect that his own thoughts may return to him from afar."—Preface to *Ges. Abh.*, etc. (Berl., 1879).

The first university establishing a full chair of pathological anatomy in Germany—Vienna not counted—was Würzburg. There and in Berlin he taught hundreds and thousands, and educated the men who were to occupy the chairs of pathological anatomy in the other universities. Rudolph Mayer, Rindfleisch, Recklinghausen, Bezold, Cohnheim, Grove, Klebs, Ponfick, and many others owe him their opportunities and their places. Since, and through him, the appearance and working of German universities have greatly changed. Through this whole long period he has worked steadily, and always more efficiently than noisily. His not rushing into print with every little observation has now and then raised the doubts of some of his former pupils, who would be gladly considered his peers, whether he worked at all. This doubt has even been expressed publicly, and, in regard to some points, he has been attacked because of his alleged want of progressiveness and thoroughness. Such is the case, for instance, in regard to the modern parasite theories of infectious diseases, and to Darwinism. Let us inquire.

Berzelius and Liebig developed the theory of chemical catalysis to such an extent that not only was organic chemistry enriched by it to a considerable degree, but the symptoms of infection (not, however, those of contagion) found a satisfactory explanation. Still, at that time, in 1854, Virchow's essay, in the first volume of his Pathology and Therapeutics, on parasitic plants, gives sufficient proof of his interest in and knowledge of the subject. A special paper of his, in the ninth volume of his *Archiv*, in 1856, demonstrated the botanical nature and classification of some forms of parasites to which an important part in nosology was to be attributed. At that time it was when he invented and first used the term of Mykosis, which has been generally accepted since.

Davaine in 1854, and Pollender, in 1855, found in anthrax the parasite which has since been given the name of Bacterium anthracis Cohn. Brauell's papers on the same subject appeared in the eleventh and fourteenth volumes of the *Archiv*, and were the forerunners of an immense literature which has since, in the *Archiv*, other journals, and independent publications, assumed vast proportions. In Virchow's hospital division it was, where Obermeier, in 1873, found the spirochæte in the blood of relapsing fever. Again, it was Virchow who, when travelling in Norway at the request of the Swedish Government, for the purpose of studying lepra, insisted upon the necessity of paying more attention to the dietetic basis of the disease, particularly to the fish eaten in large quantities. He has been severely reproached for not finding the bacillus lepræ, which, after the preparatory labors of four years, has been finally discovered by Armauer Hansen, twenty years afterward.* That very reproach proves that everybody expects everything of him, and sometimes too much. Now, the discovery of every sort of possible and impossible parasites is the regular order of the day, and has been for many years. On this side of the great water it has been Salisbury who has sharpened the appetite for numerous and uninterrupted discoveries of the kind. Every disease, every microscopic lens, every craving for notoriety, swelled the supply; endless was the number of new names, never was Greek dictionary more diligently consulted. Among the last diseases, in which Klebs and Cruvelli claim to have found vegetable parasites which at once are taken to be the very causes of the same diseases, are intermittent fever and rheumatism. Here again, Virchow has been reproached for not publicly accepting the bacilli of malaria and rheumatism. The very men who insist upon Virchow's incompetency in regard to what they consider as the only basis of the nosology of infectious and epidemic or endemic disease, still appear to address every paper they write, every little observation they publish, to him. He is expected to repeat the experiments at once, appreciate and praise the results, and come to the same conclusions. If he does not, he is incompetent. One of his best known, but not best deserving, former pupils and assistants, is Klebs, but lately an essayist before one of the London Congress sections. He appears to have proved to his entire satisfaction that his poor master ought to be his attentive pupil.

* Archiv, vol. lxxix., l. c.

Among other novelties he has found that cellular pathology is incompatible with the new gospel of the parasite theory in regard to infectious diseases. Let us hear what Virchow himself has to say about this accusation (*Archiv*, vol. lxxix., p. 209, 1880): "Klebs has placed the whole dispute on a wrong basis. Vegetable and animal parasites *are* among the causes of diseases. Their place is in *etiology*, and therefore it is easily conceived that, as Klebs expresses himself, they found no place in my cellular pathology. There it was not any more my domain to offer an extensive paper on parasites, than it was to treat of traumatic injuries and corrosions. In my cellular pathology I meant to demonstrate the changes which take place in the elements of the organism in the general forms of disease. Thus, I meant to build up a theory of the essentiality of disease. Specified causes were mentioned only as examples—for instance, intoxication; and though but briefly alluded to, parasites have not been entirely overlooked. Cellular pathology never meant to be a general pathology. If that were the case, certainly etiology would have found its place in it without abridgment."

Virchow has often been blamed for reserving his opinion, or rather not expressing it at once in favor of those who fain would have availed themselves of his approval of their rapid strides in discovery and unprecedented quickness of conclusion. We are all probably in favor of judging slowly in regard to assertions which require confirmation. For to what extent hastiness, coupled with gentle ignorance, can prove dangerous, Professor Klebs has shown but lately. In a recent number of a European journal, I find, under his name, the description of a cooking-apparatus, which is credited with keeping bacteria out of the milk which is to be boiled in it. Klebs is quite enthusiastic over it, because, as he asserts, now that bacteria can be kept out of cow's milk, no summer diarrhœa has a chance to develop itself. For summer diarrhœa is all at once, according to him, the result of millions of bacteria in the intestines of the babies, the said bacteria being the same which are found in the decomposing cow's milk. And how does he prove this sweeping assertion? Very simply indeed. While the babies had diarrhœa, he found the bacteria in the fæces, and thus he demonstrates that the diarrhœa is the result, and the only one, of the presence of bacteria. If, however, the Professor had examined the fæces of healthy babies, he might have counted the same number of millions of bacteria. The wise omission of such an examination saves his theory. Thus, if it be true that a little knowledge is a dangerous thing, I am afraid that a little ignorance is just as dangerous.

The parasite theory is not yet a scientific system. In most of its claims it is not yet sustained. Many alleged discoveries of characteristic disease-germs have seen the light in a few years, and disappeared in utter darkness. In regard to the whole question, while anxiously and willingly waiting for further facts which would simplify the pathology of infectious and contagious diseases, I still maintain, as in the preface to my "Treatise on Diphtheria" (1880), the verdict "Not proven."

Another point which has been raised against Virchow is his hesitancy in accepting not only what has been called Darwinism, but at the same time the teachings and postulations of Darwin's followers and apostles.

As early as 1849—in his "Movement in Favor of Unity in Scientific Medicine," Virchow claimed the origin of life to be a mechanical necessity. In an oration delivered in 1858, a year before the publication of Darwin's "Origin of Species"—printed in a pamphlet containing "Four Orations on Life and Disease" (Berlin, 1862)—he pointed to the changeability and transmutability of species as a necessary basis for the mechanical theory of life. Thus, he was by no means unprepared for *Darwin's* theories. But he knew—and nobody knows it better than Darwin himself—that the transmutability of species, the battle for existence, the theory of selection, even the doctrine of inheritance, were by no means Minerva's springing from the head of Jupiter, unprepared and unexpected. For Goethe and Lamarck were not unknown, and the term of self-preservation was a stock in trade of the biology of bygone times. And nobody knows better than Darwin and Virchow, that hypotheses are not facts, problems not articles of creed, and the exaggerated generalizations of enthusiastic pupils not the outgrowths of superior minds. On the other hand, much of what was twenty years ago the fear and anxiety of many men and women, has greatly settled down as established facts. Twenty years ago the pulpits teemed with attacks on Darwin and what was called his monkey-theories, mobs gathered to stone public lecturers, and extra hells were heated to consume him and his followers. For did he not intend to annihilate the belief in everything that was sacred, even Judaism and Christianity themselves? Was not religion based on the certainty that the world was created five thousand and seven hundred years ago—some thousand years after they enjoyed established civilizations in China, the East Indies, and Egypt—and was it not known that the monkey was built on Friday, and man on Saturday?

Many, most of you, remember the time quite well—it has not passed away entirely—when strong expressions were used concerning and against, the theories of Darwin and his pupils and collaborators. Many, however, are aware also that some of these pupils and collaborators fell into the same errors of expression and behavior we have to complain of in their opponents. Whoever was not with them totally, and in all their *conclusions*, was considered to be against them. And in this respect no illustrious man had to suffer more from the exaggerations of zealotism on the part of really scientific men, than Virchow.

A number of public meetings of several of the annual congresses of German physicians and naturalists, mainly those of Munich and Cassel, were taken up with a dispute principally between Virchow on one side, and Haeckel and Klebs on the other. It is mainly Haeckel to whom the popularization in Germany of Darwin's ideas and theories are due. Himself distinguished by original researches, and an enthusiastic scientist, imbued with the instinctive belief that science must fertilize individual and public life, his sustaining Darwin and his theories have greatly contributed to making what has been called Darwinism the intellectual property of most educated Germans. But in one of his public speeches he insisted upon the theories on selection being admitted among the subjects to be taught in the public schools of the most elementary character. It was to this that Virchow objected, on the ground that only established facts and results, and not theories, should be taught in schools. To this objection it was due that he was overwhelmed with reproaches. It was said that the man was so taken up with work of all

kinds, that embryology and Darwinism were sealed books to him, and that he to whom—it was true—science owed so much, was to be pitied for his advancing age, which prevented his keeping up with his former pupils, who now stood on his shoulders enjoying a larger mental horizon. These attacks on the part of Haeckel, and mainly of Klebs, are not pleasant reading. There is more eagerness and bitterness in them than we desire to meet with in scientific productions and strifes, or have ever met with in any words penned by Virchow.

There is a peculiar undercurrent to this controversy which is but rarely visible on the surface, but at the same time is readily recognized by a careful observer. To understand it, it must be remembered that German higher education is mainly classic, and irrespective of religious or anti-religious views or tendencies. The latter certainly are in the majority. Statistics do not prove that in any country and among any people, virtue, vice, and crime depend upon the presence or absence of positive creeds, be they Judaism, Christianism. or any other form of belief; but among other influences on the amount and nature of education and training. Even the anti-semitic persecutions in modern Germany have their cause, not in the prevailing influence of the Christian religion, but in the absence of schools; for it is a statistical fact that those Pomeranian and Mecklenburg districts, in which Jews are killed and Jewish windows broken and stores robbed, are less supplied with schools, and can less boast of mastering the mysteries of reading and writing, than any other part of the land of Bismarck.

Thus, it will be admitted that the mainly classic education and agnostic tendencies of the higher classes of Germans do not debar them from being good students, good men, and honest friends and enemies. But, after all, Hellenism and Latinism were human too, and Greeks and Romans hated and loved. scolded and praised, kicked and kissed, like people before and after them. There were zealots among them, too. Socrates was killed because he believed differently from other people, on the plea, however, that he subverted the State, as two thousand years afterward, the Church burned a hundred thousand adversaries. Something reminding of that has occurred in the land of free thought and profound philosophy lately. Haeckel, the classic scholar, the thorough philosopher, the original worker, is aggrieved at Virchow's not seconding all his propositions, favoring all his plans, agreeing with all his opinions and methods. There is one peculiar trait in Haeckel, too, which is rather uncommon in a German savant. His studies have been mainly in embryology and biology. His religious views are of a negative character. He believes that these ought to be strongly stated, contrary to those who think and write, that creed, faiths, and religion have nothing to do with scientific researches. With these he differs. When his book on Evolution carries him to the conclusion that there is no need of a personal God—just as Laplace said he did not require that hypothesis—he not only expresses that conclusion in strong words, but devotes a whole chapter to it. But others are of the opinion that the finding of truths and expounding them has nothing to do with the fighting of opinions and articles of faith, and that religious controversies must not form a part of scientific books. This opinion Virchow has shared all his life. More than thirty years ago (*Ges. Abh.*, p. 6) he wrote as follows:

"Faith does not admit of a scientific discussion, for science and faith exclude each other. Not to such an extent, however, that one of them renders the other an impossibility, but in such a way that within the range of science there is no place for faith, and the latter can commence only where the former ends. It need not be denied that, if this boundary line be respected, faith *may* have actual objects. It is not, therefore, the domain of science to attack faith or its objects, but its duty is to mark and consolidate the present termination of knowledge."

Such is his position this very day in regard to this question, and thus it is that much of the bitterness of feeling which appears to be engendered by strong anti-religious feelings almost as much as it is known to have generated ferocious persecutions and atrocious wars of religion, has been spent on him. He has borne it placidly, but we have to be sorry for the fact that he could not be spared it. If there is anything in science, that something is its influence in elevating, refining. humanizing, and the scientist ought to be, and will be, the very apostle of humanism. As science clears the brain, so it ought to purify the heart. Knowledge, logic, reason, ought to go hand-in-hand with feeling, sympathy, and fellowship. Let me dismiss, then, the controversy, commenced in an evil hour by a man otherwise great and good, by again quoting Virchow, who has remained true to what he expressed more than thirty years ago in the following words (*Ges. Abh.*, p. 7): "Humanism, in its true meaning, is no apotheosis of mankind—for that would be anthropomorphism—but the scientific knowledge of the manifold and various relations of the thoughtful individual man to the ever-changing world. *Its* base is the science of nature, its very expression anthropology. For that reason humanism is neither atheistic, nor pantheistic, for, in regard to everything beyond the reach of actual knowledge, there is but one formula: *I do not know* (as Liebig said, the science of nature is modest). Humanism is neither spiritualistic nor materialistic, for to *it* constancy of force and constancy of matter are facts of equal significance, and the unity of man's nature is a settled conviction. It is neither grossly egotistic nor sentimentally self-sacrificing, for, while recognizing the claim of everybody else upon existence and full development, he must demand equal rights for himself."

The humanism so well described by him, Virchow has lived up to. In his early political efforts, which necessitated his removal from Berlin to Würzburg, he showed his sympathy with the oppressed mass of the people; in his famous papers on the famine-typhus in Silesia and in the Spessar the showed his appreciation of the necessity of radical changes in the position of the neglected and starving members of society. Thus, you observe that, while engaged in professional researches, which, in regard to universality, novelty, and reforming power, are surpassed by those of none whose name is immortalized in the history of medicine, Virchow never ceased to feel that he did not only belong to abstract science, but to his people; and again, as his science has always a practical aim and result, so his political and social views have a practical bearing. He was born one of the people, and a friend of the people. He need not turn politician; he was a politician born. We, in this our country, are often in danger of forgetting that at one time, at least, the most intelligent, wise, and pure men of this nation of ours were our foremost politicians. Men of courage, character, and genius guided the rising

star of the republic through the night of despair, and the ship of state through the storms of strife and battle. Without the controlling sympathy of the very best, the Constitution of the United States would not have seen the light, and could not have been sustained to its approaching centennial anniversary. We have since descended, sometimes, to the fear that only a second-class intelligence and a third-rate morality make a successful and eager politician, losing sight of the fact that Aristotle already defined man as a "political being," and insisted upon the labor of all in the interest of all.

In many communities a politician is considered a man whose character is not above suspicion, morals doubtful, and social integrity shaky. If, however, there be any truth in this, the fault is neither in politics, nor in the politician or office-holder, but in us who feel so indifferent about our own and public matters as to close our eyes when watching is required, and to bemoan the result of an election instead of once appearing at the polls. When we happen to find a man of genius and integrity in a high or low public office, we are more apt to wonder how he came there than to feel the necessity that our offices should be filled by just such men only. Virchow's example should teach, particularly young medical men, that thorough science and good citizenship do not exclude each other. Indeed, there is nobody so removed from the midst of his fellows, so absorbed by abstract studies, but has interests in common with the rest of mankind; and nobody so raised above the level of his kind but can and ought to contribute to the elevation of his nation or race by personal contact and the attendance to daily duties. These twenty-two years Virchow has been a member of the administration of the city of Berlin. In his place as an "alderman" he has given his attention to the minutiæ of city government. A number of his papers, written within this period, treat of subjects of hygiene, drainage, canalization; and while they point to local necessities and improvements, they give the scientific reader copious material of general importance and new ideas. His regular re-election to the same place, his elevation to the vice-presidency of the board, prove two things: first, that his efforts in the direction of turning science into practice are appreciated by the population of his city; and secondly, that he is not tiring of keeping up his contact with his fellow-citizens, of feeling his obligation to the commonwealth, and acknowledging his duties to his neighbors; and that much, as the Scriptures have it, is demanded of the man to whom much is given.

But more. A man of his attainments can be made useful in a wider sphere; a man of his sense of responsibility will shoulder more important duties. Since 1862 he served in a constant succession of terms as a representative of the people of Berlin, in the Prussian Lower House. In this capacity he acted as a member of finance and other committees, always ready to work, to learn, and to teach.

However, to go into his history as a politician would require a review of Prussian and German politics. This may be said only, that, though he be not at all a brilliant speaker, his words are always listened to with attention, his wisdom is always honored, his courage and moderation are always admired. It is not necessary to add that he sides with the party of liberal views and progressive tendencies, and is in constant opposition to the one man who, through nearly twenty years of oppressive measures, dissolution of parliaments, governing without the assent of the representatives of the people, sudden changes both of economical and ecclesiastical policy and party affiliations, brutal assaults on the rights of individuals, the freedom of the press, and the principles of the constitution, though he succeeded in throwing into the lap of the Prussian reigning family an addition of large territories, and gaining for Germany a partial unity, done more than any German man in history to emasculate German politics and demoralize the public conscience. I am no prophet, but this I predict: when that man of iron and blood will have closed his career, no sorrowing fifty millions will drape their doors, as we did a week ago, and feel that every household has been bereaved, as we then felt. A seat in high politics will be vacant, but no place in the hearts of the people will need to be filled. Bismarck has not found a more persistent and conscientious adversary than Virchow through all his parliamentary career. In regard to the latter I will predict that among the German politicians who resisted, to the utmost, lawlessness of absolutism, and claimed that law should be supreme, the rights of citizens respected, the office-holders know and live up to their duties, the constitution be carefully guarded and protected, and peace not rendered as expensive and exhausting as war, Virchow's name will, for all time, be mentioned among the first and wisest and purest.

Did time permit, I would fain go into particulars: his contributions to the legislature on infectious animal diseases; on fisheries; his participation in the debates and legislation on the arbitrary expulsion of Jesuits; of his introduction of the term "Kulturkampf"—battle for culture—in connection with the dissensions between Bismarck and the Pope, which commenced with the boast of the former that he would not go to Canossa, and ended with the victory of the latter four weeks ago; his many lectures for workingmen's societies; his superintending, with Prof. Holtzendorff, the fortnightly publication of a number of series of popular lectures; his supervising the erection of public hospitals and the first barracks; his conducting the first sanitary train into France during the Franco-German war, and his serving as an officer in the army auxiliary societies centred in Berlin.*

When he first became noted in politics the admirers of his genius became anxious concerning the influence politics might exert on the rest of his labors. There were those who predicted that politics meant the closing of his scientific career, and others—not rarely those who owed him their education, first ideas, and positions—jealous of the great king's powers, who supplied the cartmen with jobs while he was building—as Schiller has it—took it for granted that he could not even keep up with the rapid strides special branches of science were making through their and others' efforts. But the facts point the other way. Since he almost filled the first volume of his *Archiv* with his introductory "On the Standpoints in Scientific Medicine," and his researches "On the Development of Cancer," and "On Pathological Pigments," and an "Essay on the Reform of Pathology and Therapeutics by Microscopical Investigations," almost no volume has appeared to which he has not himself contributed. Many of his papers are elaborate and lengthy, and would, if written by most others, according to the habit prevail-

* One of the latest cable news speaks of Virchow as one of the speakers in a public meeting held in memory of James A. Garfield.

ing in Germany, have swelled the number of pamphlets and books published with independent title-pages, instead of forming parts of journals. Gigantic work like that performed by him in his first twenty years cannot continue forever; one new era created cannot be replaced by another by one man. If he had done nothing since besides writing his occasional reviews and summaries, such as, "Old and New Vitalism" (vol. ix.); "Our Programme" (vol. l.); "War and Science" (vol. li.); "On the Standpoints in Scientific Medicine" (vol. lxx., 1877, thirty years after his first article in the *Archiv*); "The Nature and Causes of Disease" (vol. lxxix.), he would have deserved the thanks of the medical world. That he has done more, we know. Some remarks of his own in regard to the subject are found in the preface to his first volume on tumors, and are very characteristic. He says:

"The dates of many of my lectures will prove that even on those days on which important matters claimed the attention of Parliament, I have attended to my duties as a teacher. To set at rest the anxiety of my friends, I will add that the silent and often unnoticed labor of a scientist requires more energy and greater effort than the activity of the politician, which is both noisier and more speedily appreciated. The latter has appeared to me often to be rather a recreation than otherwise."

Of such "recreations," as Virchow calls them, he has, however, more than one. His practice among the forlorn herdsmen of Asia Minor is an instance.

Schliemann, by whose modern witchcraft holy old Troy is just leaving its tomb, invited Virchow to aid him in his work of discovery of the buried city. He went—partly to aid, partly, as he says, to escape from overwhelming labors at home, only to be engrossed in just as hard work, though of a different nature. In regard to the latter, Schliemann's recent book on *Ilios* contains some very interesting material. But what has engaged my attention and interest most has been to observe the humanity and indefatigability displayed by the great man in the service of the poor and sick. To read of his constant practical exertions in behalf of the miserable population of Hissarlik, how he taught the aborigines the efficacy of chamomile and juniper, which grow about them, unnoticed and unused, in rare abundance; how a spring he laid open for archæological purposes has been called by them the physician's well, and is believed to have beneficial effects; how he was, on leaving the neighborhood, loaded with flowers, the only thing they had and knew would please him, has charmed me intensely. To admire a great man for his professional labors, eagerly undertaken and successfully carried out, is a great satisfaction to the scientific observer; to be able to love him in addition, for his philanthropy and warm-heartedness, is a feast of the soul.

On this platform, and on the seats in front of me, there are masters of our profession, not a few known wherever medical science and art are appreciated, studied, and practised. There is, however, none among them but has learned from the great genius whose name I have so often mentioned in the course of this hour. There are practitioners here, learned, shrewd, successful; every one of them uses the terms invented, knows the theories proposed by the same powerful mind. Those who are young have grown up under the shadow of this tree; those who are old have been taught by him to look through his eyes and follow his methods. Schools have been overturned by his efforts, science and scientific method reign supreme. The last dangerous doctrine of the crases of the blood, so long upheld by Rokitanski, belongs to the past. Pathology is, since and through Virchow, founded on the smallest organism—the cell—and is, as Huxley but recently proclaimed it, nothing but that branch of biology which treats of peculiar disorders of cellular life, or of the co-ordination of cell-complexes, that give rise to every vital process. We cannot to-day read a medical book or monograph without Virchow's name being inscribed on many pages. When it is not mentioned, it is because the facts have become as self-understood, almost, as a mathematical axiom or an occurrence in history. There are hundreds of journal articles in our literature commencing with the phrase, "Virchow says." Modern medicine without his name cannot be written. They belong together. Nevertheless, I repeat, his is not a school. His methods are simply scientific, based on facts and leading to facts. Schools are built on ingenious ideas, not based on facts and experiments. It is not probable, I cannot imagine, that after the schools of Broussais and Brown and Schönlein, and that of Vienna, there will be another one. Our school, the school of the future, is scientific medicine. The greatest glory of Virchow, for all time, is that he was too great to establish one, and too universal to compel us to *jurare in verba magistri*. All of us, old, or young, knowingly and unknowingly, are his pupils. The young men who to-night enter upon the study of medicine will hardly be taught a chapter in pathology which does not exhibit the impress of his genius.

Was I right in presenting, as an ideal pathologist, this man to the old and young engaged in medicine, and particularly those here this evening? Virchow has done enough to immortalize his name by his researches and the progress medicine has made through him. His rank in the history of medicine *is* assured. Among archæologists, also, he ranks high. The Anthropological German Society made him president after the first year of its existence. Schliemann calls him to Troy to avail himself of his superior knowledge. Numerous discoveries among old tombs, and valuable essays, are due to him. His scientific mind and exact methods prove as successful in archæology as in pathology. Even purely historical researches, as those undertaken of late on the battle-field of Fehrbellin, owe him their success.

His position in politics, his participation in all humane endeavors, I have alluded to. No longer is he to us only the man of pure science, but also the practical statesman and philanthropist. Moreover, he is the practitioner of medicine among the poor, like the best and noblest of us.

Thus, we have in him a man who has done more for pathology then any single dead or living man. He has been foremost in raising, when the time was ripe for it, medicine to the dignity of a science, with purely scientific methods. He has served his country as he did science, and humanity as he has his country. Was I right in speaking of him in the first hour of your medical studies, young men, as the ideal of a medical man, and a man? There is but one thing I have to add—it is this: that, as a rule, biographies are given, and held up to admiration and imitation when great men have long completed their labors with their lives. Let us rejoice that Virchow's biography is not completed yet, and that he will, I hope, long live to contribute to medical science, as your teacher and the teacher of your teachers.

# Original Communications.

## TREATMENT OF SUBACUTE AND CHRONIC GOUT.

By ALEXANDER HADDEN, M.D.,

VISITING PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, NEW YORK.

Since the publication of my article on subacute and chronic gout, in this journal of April 17, 1880, I have pursued the same line of inquiry and practice in the management of these painful and obstinate conditions, with such results as will be in the following cases set forth:

Case I.—T. M——, aged thirty-five, stonecutter, married, native of Ireland; admitted into the Presbyterian Hospital, September 11, 1880, suffering from subacute gout. He gives no hereditary history of the affection; was healthy until seven years ago, when he was seized with malarial fever, from which he recovered in a short time. Three years afterward had an attack of acute articular rheumatism, lasting for three weeks; has since had rheumatism, as it has been called, but which seems to have been subacute gout, leaving deformity of wrists, fingers and ankles. On admission, complains of severe pains in the shoulder and hands, which were swollen and sensitive upon pressure. Is unable to flex his fore-arm on his arm. Has constipation, anorexia, restless nights, and occasional pain in the joints. Joints of feet and hands thickened, and the seat of deposits of urate of soda is somewhat emaciated. Urine upon examination was found acid, sp. gr. 1010, no albumen, no casts. Deposits of urate of soda quite abundant. Was put upon the usual anti-rheumatic treatment without any improvement.

October 6th, came under my care suffering considerable pain; hands and feet swollen, red, and some pain and swelling in the other joints. Evidences of the urates of soda deposits in many of the joints. Temperature a little above normal. Urine alkaline, sp. gr. 1010. On microscopic examination, deposits of the urate of soda were found. Bowels were constipated.

Treatment ordered: To relieve the constipation a four-grain pill of comp. colocynth at night. Weak alkaline washes were applied to the painful members. Was given five grains salcy. soda three times a day after eating, and opiates in sufficient quantities to secure rest. Was put upon animal diet, with the exception of such vegetables as possess neither amylaceous nor saccharine principles. On the 20th the acute pain had nearly subsided; has greatly better motion in feet and hands; can walk without much difficulty; is comfortable nights without opiates; is not troubled with flatulence. On 26th was discharged, feeling quite well.

Case II.—G. A——, aged forty-eight, butcher, married, native of England; admitted November 16, 1880, suffering from subacute gout. Has had previous attacks; wrists, elbows, and shoulders of the right side, both knees and ankles, and hands were affected, and had gouty deposits in the smaller joints, and other evidences in the urine and alimentary canal of gout were present. Was placed upon the treatment on 17th, as above mentioned. Urates disappeared from the urine in a few days, and became otherwise quite normal. Patient went on without interruption through convalescence. December 9th, discharged, feeling well.

Case III.—J. D——, aged fifty; painter, widower, native of Ireland; admitted January 13th, suffering from subacute gout. Wrists and hands swollen and inflamed; urates of soda, the phosphates, and oxalates were found in the urine in great abundance. On 25th the same treatment was applied. February 11th, no urates in urine; much improved. March 13th, discharged improved, with hands and feet in good condition.

Case IV.—E. G. W——, aged sixty; lawyer, single, native of New York; admitted December 16, 1880. Has not been intemperate nor had venereal disease. Has no hereditary history of the affection. Ankles swollen; urates in urine, no albumen, no casts; sp. gr. 1020. December 20th.—Diminution of the urates, less pain, better appetite. December 30th.—Urine nearly free from urates; less pain in the joints. January 13, 1881.—Some œdema of the ankles; bandages applied. January 14th.—No pain; joints more mobile. January 20th.—Urates have entirely disappeared. Discharged, very much improved.

Case V.—Mrs. G——, aged fifty-seven, native of Scotland, married; a free liver; is in the habit of drinking considerable malt liquor. Does not inherit gout. Has been subject to a number of attacks of it during the past ten or twelve years. Came under my care, September 20th, for treatment of an attack of the same; quite acute. Suffered the ordinary intestinal symptoms; somewhat reduced in flesh; bowels constipated; feet much swollen; smaller joints of feet greatly so. Joints of thumb, wrist, and elbow had each of them gouty deposits, or tophi; specific gravity of urine, 1012; traces of albumen; no casts. Swollen members were bandaged with cloths wrung out of alkaline water slightly warmed. Cathartic of comp. colocynth, five grains, at night, and salcy. soda five grains four times a day. Opiates to quiet the pain at night. Put upon the diet as previously given. October 1st.—Had greatly improved; no urates now in the urine, and all traces of albumen disappeared. Some pain in joints, some œdema. November 1st.—Entirely well, same diet being continued throughout. I saw her a short time since (September 10, 1881), and she says she has had no return of the gout; health good. She continues the diet under protest.

Case VI.—T. O. H——, aged forty-one, grocer, married, native of New York; admitted July 27, 1881, suffering from what was thought to be gonorrhœal rheumatism. Joints of hands and feet both swollen and painful. Was weak. Was put upon the usual anti-rheumatic remedies, and continued on these up to August 20th. At this time the urine was examined, and found to be of light specific gravity; some albumen; urates of soda in abundance. Was confined to bed. Joints of hands, feet and knees painful; swelled and thickened with gouty deposits. Tophi in the outer margin of the external ear. Was put upon the diet already described, and a bandage wet with a weak alkaline solution wrapped around hands and feet. Was given salcy. soda three times a day after eating. Bowels, which had been alternately relaxed and constipated, were relieved by comp. colocynth pills. Fifteen days thereafter the urates of soda entirely disappeared. Hands almost entirely relieved of pain and swelling; knees and other members also, with the exception of the right foot, which remained swollen, but not painful. Urates have not reappeared in the urine up to this time. September 20th.—Is walking around, one foot slightly swollen and stiff; otherwise in good condition; appetite good, bowels regular, and is increasing in weight.

It will be seen from the above that the withdrawal from our diet of the saccharine and amylaceous food, and the free use of animal diet, has acted beneficially in the treatment of patients suffering from subacute and chronic gout; therefore it is reasonable to infer that this kind of food may be a factor in the production of this disease in the human system, as well as other well-recognized causes.

Garrod gives among his predisposing causes of gout, malt liquors and wines, even the light wines, and says that their free indulgence for several years will bring on the disease in those who have not derived it from their ancestors, and also that port enjoys a very marked reputation in this respect, and that sherry, however dry, is by no means an innocent beverage, so far as gout is concerned. He also states that malt liquors predispose strongly to the production of gout, and supports his statement by the hospital reports of the large cities in England, where porter and other malt liquors are much indulged in by the laboring classes who are there treated. Even that the pale bitter ales, to many so grateful, will, freely indulged in, give rise to gout. Of cider, he says, the fully fermented—that in which the saccharine matter has been gotten rid of—has little power. Sweet and partially fermented cider predisposes to gout; and in that declaration Dr. G. has the opinion of all good observers to support him, and about every writer on the subject. Facts and opinions such as these may be indefinitely continued; but as they only serve to illustrate that he is supported, I will not pursue them farther. Such being the case, I have hoped that during the past year some physiological experiments would have been made that would either have confirmed or disproved the hypothesis advanced in the last paragraph of my published article on this subject, but up to this time I have seen nothing to either confirm or disprove it. It stands only as a clinical fact.

To briefly quote the hypothesis then made: "Whether some fermentation may not take place in the alimentary canal of such animals, birds, and human beings as subsist largely upon a diet composed mainly of amylaceous and saccharine principles, or both, similar to the fermentation which takes place in the manufacture of malt liquors or wines, etc.?" It is true, that the carnivorous animals and birds are entirely free from gout, or any enlargements resembling the disease in parts most likely to be attacked. I have examined the joints of a great many of them; some of them wild and in a state of nature, others in captivity, and which had been so for fifteen or twenty years, and still remained free from gouty deposits; also those domesticated, and the same condition was to be observed. I have also examined the herbivora, or those subsisting largely upon amylaceous and saccharine foods. In the horse, which is perhaps the most highly fed of any of the domestic animals, may be seen enlargements of the joints; those enlargements which are known to farriers as spavin and ringbone. The deposits to which these enlargements are owing, I have examined microscopically, and they have been found to be composed of a substratum resembling the hippurate of soda. These enlargements are not all, of course of this character, some are the results of sprains and other injuries; but I refer to such as are from none of these causes, but which are blood diseases, inherited and acquired. Several of these specimens may now be seen in the museum of the Columbia Veterinary College. Cows and sheep, when highly fed, are also subject to this condition, as I am told by parties having the care of stock of this kind.

To the evidence of Seidangrotzki, that pigeons are subject to gouty deposits in their metatarsal and tarso-phalangeal joints, we will here add the testimony of M. Méguin, who states that parrots die of gout; that in their digital and tarsal articulations are veritable gouty *tophi*. The microscope shows that the substance of which they are composed is urate of soda. This species of birds is purely granivorous, but M. Méguin attributes it to their confined and caged condition, and their inability to indulge in their natural freedom. This cause is evidently not the true one, for pigeons, which have their natural freedom, barnyard fowls, and the grain-eating birds generally, suffer and die of gout, as do parrots, and they certainly enjoy the greatest amount of freedom.

## SKIMMED MILK AS AN ARTICLE OF FOOD.

By E. F. BRUSH, M.D.,

FELLOW OF THE NEW YORK ACADEMY OF MEDICINE, MEMBER OF THE WESTCHESTER COUNTY MEDICAL SOCIETY, ETC., ETC.

The position occupied by health authorities in this country in relation to the milk question is unscientific and fails in its primary object, the preservation of public health. Reviewing the action of the health authorities of New York city, one cannot avoid the impression that in their opinion the addition of water or the subtraction of cream are the causes of the high rate of infant mortality. As an illustration, let us take this report from The Medical Record of September 17th: "A recent outbreak of a mild form of typhoid fever in the Roman Catholic Orphan Asylum in this city was ascribed to the poor quality of the milk furnished for the children. An analysis, made under the direction of the City Board of Health, by Dr. C. E. Munsell, gave the following result: Temperature, 60° F.; lactometer, 109; cream, per cent., 4; water, per cent., 88.69; fat, per cent., 2.64; casein and sugar, per cent., 8; salts, .68. This showed that the milk was skimmed and probably watered." Leaving out of consideration all the elements except water, we find, according to other authorities, that this milk contained less water than what we are led to believe usually occurs in milk. Wanklyn gives, for ordinary country milk, the proportion of water 90.09, or 1.40 more than Munsell's typhoid-breeding milk. For average town milk the same analyzer gives the figures 88.43, and for the Aldeney, which is always reckoned the richest of all, he gives 89.88, or 1.19 more of water than the above so called unhealthy milk. Other authorities, needless to quote, give equally high proportions of water. But even supposing that the milk in question had been skimmed and watered, does any scientific man think that after the process the milk would be injurious or innutritious? There is no doubt that the milk of all the cud-chewing animals contains a much larger proportion of solid matter than Nature intended for this variety of food for proper digestion in the stomachs of the non-cud-chewers. In the feeding of infants mothers are often advised to add as much as one-third water to cow's milk, but even this does not lower its solids to correspond with human milk. Let us, therefore, as honest scientific men, cease to account for disease by the addition of water to milk. It is equally absurd to call skimmed milk unwholesome. Every scientific man who has given the matter thought has arrived at the conclusion that all milks contain more fat than is necessary. Even the young of the animal whose milk we use is never fed

on whole milk after the first week, or when the colostrum ceases to be secreted. Professor Johnson, a practical agriculturist, says of the calf: "It requires the nitrogenized principles more than the fat, and hence half the milk it receives should be skimmed. In fact, calves raised entirely on skimmed milk are healthier than those allowed to get the whole milk from their mothers." Charles L. Flint, Secretary of the Massachusetts State Board of Agriculture, and a practical farmer, after stating that the calf should invariably receive the colostrum from its mother, adds, "when it ceases the milk should be skimmed." This he gives as his own practical experience. I know the instance of a man who fed his calves with the entire whole milk of their mothers, and they all died that season. Since then he has given them less milk with some fat abstracted, and none of them have died in the same manner. This does not indicate that Nature does not understand her work. Our cows are not in a state of nature. We keep the mammary glands in a state of over-excitement, which, no doubt, has modified the secretion. The fact has been also satisfactorily established that woman's milk, which contains much less fat than cow's milk, contains more than is necessary for the sustenance of her child. Professor Jacobi, perhaps the most eminent authority on the subject that we possess, states explicitly: "When no food is given but mother's milk, which contains fat in proportionately smaller quantities than cow's milk, finely suspended and easily absorbed, a good deal of fat is eliminated without any change. Cow's milk contains more butter than human milk; if the latter, as stated above, is not entirely digested, cow's milk butter will certainly leave even more remnants to encumber the intestinal canal." Ewald, in his lectures on digestion, also forces this fact upon us in the following words: "The so-called milk detritus that is so often found in the shape of yellowish-white flocculi in the stools of healthy infants, consists, according to Wegscheider, far more of fat, and, indeed, of oleine, palmitine, stearine, and a little peptone, than of unchanged albumen. Liebig undoubtedly understood this fact of milk containing more fat than was necessary, and therefore proposed, in the preparation of artificial human milk, the use of skimmed milk of the cow. Let no one misunderstand me in relating the above facts. This is not a plea for dishonest milkmen, but rather an earnest protest against the misdirected energy of some of our health officers. With the exception of stopping the sale of milk from the Blissville stables a short time ago, I have been unable to discover a single instance where our health authorities have found poisonous milk from diseased animals.

Let us now consider what skimmed milk is, as sold in the cities. In the first place, it is much more apt to be the produce of healthy cows, from the fact that the milk of diseased animals has to be disposed of at once because it cannot be kept long enough for the cream to rise in paying quantity. Furthermore, practical butter-makers have discovered that butter must be made from the milk of healthy cows. Again, the amount of cream abstracted from milk sent to the city for sale is necessarily small, from the fact that the milk must be kept at a low temperature in order that it may not sour before delivery to customers. I found, in one of the agricultural reports, the statements of a man who visited the creameries at the instance of the State Board of Agriculture, that the proportion of butter made from the cream of the skimmed milk sent to the city was one pound of butter for the hundred pounds of milk. It is also a fact that these creameries are very cautious as to the milk they receive, as they not only test it for dilution, but also as to its odor in the water-bath, which they declare from practical experience indicates certain diseased conditions of the milk. I am aware of the fact that there is another mode of extracting the cream besides skimming, namely: by a centrifugal machine; but after diligent search I have been unable to discover one in operation. My search has, I may state, been confined to Passaic County, New Jersey, and Westchester County, New York. But even it, I am convinced, does not abstract all the cream. One of the properties of albumen—that little understood element of milk—is to hold a certain amount of fat in solution and always to prevent it rising in the form of cream copiously. This fact led Professor Hayes to suggest that the only way to get all the fat from milk was to churn the whole milk instead of the cream alone. In some districts they warm the milk before churning, as they find that in this way they obtain far more butter than by any other proceeding.

Therefore, taking all things into consideration, skimmed milk always contains a fair proportion of fat, and is undoubtedly one of the most nutritious foods we have. It is, therefore, with shame and indignation that I read in to-day's paper the announcement that one hundred and fourteen cans of milk, supposed to be skimmed, was thrown away. In all moderation this cannot be called anything but downright sin and wanton waste. The 1,140 gallons thus destroyed represented so much waste time, waste labor, waste fodder, and life. If they had been made into cheese, they would have produced 836 pounds. It is not presumable that the Board of Health could thus have used up this quantity, but might it not have a special milk-wagon for such contingencies and sell the confiscated milk at a nominal price in the poorer districts of the city? To families receiving a pint of milk a day, this cuts off the supply from over nine thousand families. This is an extreme estimate, but supposing it were only one thousand, the evil would be worth remedying. Do the gentlemen composing the Board think how many babies will, in consequence of their action, pass this day on a short allowance of milk, or what disease and mortality may be caused by the substitutes which poor parents will have to supply to their children in lieu of the milk thus wantonly destroyed? Would it not be well, also, for them to recognize that, after long-continued droughts, like the present, the supply of milk is much lessened, and the temptation to water increased? I have known milk reach the price of $10 a can after one of these raids, as we may justly call them, which invariably occur at a season when the supply is limited. I must again beg not to be misunderstood. I do not advocate, as you know, fraudulent sales of skimmed milk as unskimmed, but I protest against the waste and the train of suffering consequent on the destruction of so much valuable food.

After years of serious thought on this subject and attentive study of the laws relating thereto, I am convinced that there is much that is wrong, much that is deficient, in our legislation. In fact the whole law needs remodelling. As an outline of what I would consider an improved system of milk laws, I would suggest:

*First.*—That all city milk-dealers be compelled to procure a license from the Board of Health.

*Second.*—That all city milk-dealers report to the

Board the quantity of milk they sell and where it is obtained.

*Third.*—That in the death certificates of all children under two years of age dying from certain specified forms of disease, the name of the milkman supplying them be inserted.

By some such system the Board of Health would be able to detect really poisonous milk. If a certain form of infantile trouble was found to prevail among the customers of a certain milkman, an inspector could be sent to the source from which the milk came to ascertain if there had been an epidemic in the dairy, or if any of the cattle were suffering from any disease. After a few years of observations thus carried on, the health authorities would be in a position to propose laws regulating the sale of milk from diseased animals and infected dairies. We would thus come to understand intelligently, what I with shame confess we do not, the highest type of food which bountiful Nature has given us. I am thoroughly convinced of one fact, that the sale of poisonous milk in New York city produces more trouble than if the whole supply was pure, healthy skimmed milk.

MOUNT VERNON, NEW YORK.

## SUBSTITUTIVE MEMBRANE IN THE AURAL CANAL.

BY FRANCIS VALK, M.D.,

NEW YORK.

THIS is a result that may occur in the treatment of suppuration of the middle ear, which is most "devoutly to be wished," as though seldom occurring during the course of treatment, yet in those fortunate cases it protects the patient from any further danger, so that the aural surgeon should look for such a result and promote it by all the means in his power, that he may assure his patient that he is well and thoroughly cured, and that the existing impairment of hearing must be borne with. I have met with two cases of this nature, and their results may be of interest to the profession. The subject was also mentioned by Dr. Samuel Sexton in his discussion of Dr. Clinton Wagner's paper on "Habitual Mouth-Breathing," at the meeting of the County Medical Society, and published in THE MEDICAL RECORD of June 11, 1881, although I judge that his cases were the results of healing in a large perforation of the membrana tympani. These two cases occurred, one in hospital and the other in private practice, and will show that a complete cure of suppuration of the middle ear may occur, by which, although the patient cannot have his hearing restored to the normal standard, for the injury already existing to the parts involved; yet he will be secure from any return, or the dangers that may occur from the condition of the middle ear. I refer to those cases in which the membrane and ossicles have been swept away in the course of the disease.

The first case I saw, Miss E. B——, aged twenty-four, a well-developed young woman, presented herself at Prof. Roosa's clinic, at the Manhattan Eye and Ear Hospital, and was assigned to myself for her history and treatment, which was as follows: She was vaccinated at the age of four years, so the mother says, and shortly after the ears commenced to discharge matter, with occasional earache, for which she used flaxseed poultices and laudanum, which relieved the pain for the time, but the discharge still continued for five years, when it seemed to stop, and at present she complains of slight pains, constant tinnitus aurium in both ears, and hearing impaired, particularly on rainy days. On testing with the watch, which should be heard at twenty-four inches, I found it H. D. R., $\frac{2}{24}$; H. D. L., $\frac{\text{scarcely}}{24}$, while tuning-fork was heard well in both ears, when placed on the mastoid region. She has been troubled with nasopharyngeal catarrh for several years, although the mouths of the Eustachian tubes appear healthy. On examination of the left ear the canal was found to be half full of hard black wax, which I removed with the syringe and warm water, and then noticed a loose portion in the bottom of the canal, which I removed with forceps, and found it to be a cup-shaped mass of epithelial scales matted together, so that it came out entire. The bottom of the canal then presented a new-formed drum of healthy tissue, a neoplasm extending across and completely closing the canal at about the normal position of the drum-membrane, perfectly smooth and even externally, and deeply concave. This neoplasm had a few white striæ pointing toward the centre, and some minute blood-vessels running in the same direction. On touching it with a very fine probe the periphery seemed to be cartilaginous, and the centre, for a space about one-eighth inch in diameter, was thin, elastic, and could be easily moved by Valsalva's method, or with Leigle's otoscope, and must have vibrated to the wave sounds somewhat. The right canal presented the same neoplasm, only it was situated somewhat externally, a little behind the junction of the cartilaginous with the bony canal. After inflation of the middle ears by the catheter and Politzer's method, which was readily done, as the Eustachian tubes were pervious, the hearing was increased to H. D. R., $\frac{1}{4}$; H. D. L., $\frac{3}{4}$. She did not return for treatment, which might have improved the hearing very much.

The second case, occurring in my private practice, was Mr. L. B. V——, an architect of this city, aged forty, who consulted me in January, 1879, for suppuration of the middle ear, existing since an attack of scarlatina during childhood, and having tried several methods of treatment with no success, had about resigned himself to his condition, with impaired hearing and a very profuse discharge from both ears. Wishing to have his life insured in one of our large companies, he was refused as a bad risk until his ears were well. He then decided to make one more trial, and came to my office at the above date, when I found his hearing very poor, being *nil* in the right ear, and only $\frac{1}{4}$ in the left. On cleansing the ears I found large polypi filling one-half of the canals, which I carefully removed with Wilde's snare, and then found that there was no vestige of the drum or ossicles left—all swept away—and the tympanic cavity exposed. The bases of these polypi were touched with monochloracetic acid, and after inflation his hearing was very much improved, particularly in the left, which was $\frac{3}{4}$. The treatment was continued until the suppuration gradually stopped, and I noticed a rim of new-formed tissue growing around the canal at the position of the drum, which gradually extended in both ears until it completely closed up, forming a neoplasm, or substitutive drum-membrane, that completely and efficiently protected the delicate parts of the inner ear. At the present time, now two years since treatment, the ears are perfectly comfortable. There is no sign of any return of the suppuration, and hearing is much improved, compared to its condition before treatment, though it is not quite as good as when under

treatment. These neoplasms closed up, but I have advised him to let the ears alone, as, though an opening might improve the hearing, at the same time there would be great danger of a return of the old affection, with, perhaps, serious results. I cannot say that there was any special course adopted to bring about this result, but they have proved very interesting, and show that should this substitutive membrane appear and entirely close, we may consider it a radical cure of a most distressing and dangerous disease, that may affect the life of our patient —a disease that should receive constant care and attention, so long as the discharge continues and the inner ear is exposed, as I believe all cases will entirely yield to proper and skilful treatment.

233 East Thirty-fifth Street, New York.

## Progress of Medical Science.

The Heart Symptoms of Chorea.—Dr. Octavius Sturges (*Brain*, July, 1881) regards the heart symptoms of chorea, taking them in their entirety, and not by arbitrary selection—the early irregularity, the variable mitral murmur, the very frequent acceleration of heart and pulse, with frequent fluctuations in the rate of both—as being altogether special and peculiar. They are signs of the heart's sympathy with the voluntary muscles, and are seen most frequently at that early time of life when the antecedence of acute rheumatism is the least probable. The heart suffers, by whatever mechanism or nervous influence, together with the rest of the muscular system, or rather it is apt to suffer. In order to understand the conduct of the heart in chorea, we must look to the disease itself and the modifications it exhibits at various ages. The heart is apt to sympathize with the voluntary muscles at all ages, up to the adult period, this sympathy being shown as well by dynamic murmur as by accelerated action, unevenness of rhythm, and not seldom the excited impulse common in hysteria, the particular manner of response being dependent upon the age of the patient. The hypothesis is that these several modes of cardiac affection correspond with as many modifications of chorea, which are exhibited not in the heart only, but in the voluntary muscles as well; these several regions sharing jointly, each in its own degree and after its own manner, in a disorder the area of whose influence is co-extensive with that of ordinary emotional disturbance, and particularly that in all such variations the motor element of the affection is represented mainly by irregularity and unevenness of cardiac rhythm, the emotion element by acceleration, and the paresis element by dynamic murmur.

Intermittent Aphasia (Epileptiform Attacks).—This case, reported by Dr. S. G. Webber, in the *Boston Medical and Surgical Journal*, August 11, 1881, is rather unusual in several respects. The patient, a man aged fifty-four years, who had for many years suffered from periodical headaches, had had several attacks of aphasia, with no loss of power, and apparently no other disturbance of function. As there was also loss of power to write, from the inability to conceive the words and transmit the verbal ideas to the hands, not from inability to hold a pen or move the fingers, it is impossible to know how much disturbance of mental function there was. Yet there must have been at least a limited power for mental action; thus, he was attacked suddenly in a friend's counting-room with inability to talk; he knew enough to recognize the attack, to take his hat and go to his own shop, then to go to the cars, to take the right one out of many, to pay his fare, and to reach his destination entirely unaided. All this was possibly somewhat automatic, yet there must have been considerable cerebral control to carry out such a long-continued course of automatic action.

When seen he had nearly recovered from an attack; he talked in a restrained manner; his memory seemed to be poor; he was irritable; his pupils were about one-sixteenth of an inch in diameter, and did not dilate when the light was diminished; the eyes moved naturally, and there seemed to be no impairment of vision; his tongue was protruded straight; the motion of both hands was the same, but they were a little unsteady; he walked naturally and well, even with the eyes shut; he stood on the right foot rather more easily than on the left, with the eyes shut, but the difference was very slight. Sensation was a little more acute on the right than the left in hands and legs; on the face it was diminished; hearing was slightly better with the left ear, but not good with either; there was no tenderness over the spine, nor over the sympathetic ganglia in the neck; his head was feeling badly from a sense of pressure across his forehead. He was not seen again for nearly two weeks, during which time there had been no new attack. Then he seemed better, but still he lost a word occasionally in talking; his memory was improved.

A little more than two weeks later he had a slight attack, and in a week more a severe one. Between these two he had not been quite so well, he had been somewhat excited, especially in regard to business matters, had slept poorly, but the day before the severe attack was quiet and calm. In the morning he went to his business, and returned home in the afternoon. He was unable to talk, could only say "yes" and "no;" saliva ran from his mouth, he had a dose of bromide and went to sleep. He was seen at six P.M., was quiet, face rather flushed; could not talk connectedly, was especially troubled with using nouns, at times he used wrong words, did not seem disturbed at it, even smiled at his mistakes, when the right word was mentioned, he recognized it and seemed pleased; pulse, 90 to 96; temperature under left axilla, 100° F.; under right, 101° F.; a pencil and paper were given him, but he could not write. The next morning he talked well; pulse, 72; a slight loss of tone was then noticed in the muscles on the right side of the face; he could then stand on the left foot with his eyes shut better than on the right. He subsequently was removed to an asylum, where he died. At the autopsy there was a limited amount of softening of the isle of Riel and the sphenoidal lobe on the left, and to a less extent on the right. This softening was in part post-mortem. The changes in the blood-vessels were marked, particularly as regards the middle coat of the smaller arteries, which was entirely transformed into a calcareous sheath encircling the vessel; there was a slight shrinking or atrophy of the external layers; the larger arteries were healthy. In several places the pia mater was adherent, tearing off with itself thin layers of the gray substance. The brain-cells in the softened parts were darkly pigmented and contained fat-globules.

Dr. Webber attributed the aphasia to the disturbance of circulation caused by the disease of the small blood-vessels, and not to the gross lesions of the brain-substance.

On Insomnia and Other Troubles Connected with Sleep in Persons of Gouty Disposition.—Dr. Dyce Duckworth treats of this subject in *Brain*, July, 1881, from a clinical standpoint. The simplest form of insomnia which occurs in persons who are goutily disposed, is due in most instances to dyspepsia. This sleeplessness is often caused by some particular article of diet which the sufferer digests imperfectly, or may be due to excess of wine, or mixing of various liquors. Other forms of gouty trouble manifest themselves not uncommonly in the early hours of the morning. Thus, attacks of bronchitis, with asthmatic dyspnœa, sometimes replace or alternate with regular onsets of gout, and the paroxysms of asthma are very prone to begin, and to disturb the patient after midnight. Startings and shoutings have been noted, associated or not, with the dyspepsia preceding or accompanying gout. Severe and troublesome priapism in the night sometimes greatly annoys the gouty, commonly without erotic feelings. Grinding of the teeth during sleep is a symptom met with in those who are gouty. Many of the special determinations of the malady take place during the night, whether the sleep be disturbed or not. The patient retires to bed feeling in his usual health, but on awaking in the morning he discovers at once some new phase of his malady: it may be muscular pain or stiffness, angina of the fauces, the beginning of a hemicrania, or more or less severe pain in some point or adjacent texture, such as a stiff neck, lumbago, or a burning pain in a phalangeal joint. These troubles, or some of them, have come on in the night, but have not been sufficient to disturb sleep. Cramps in the calves of the legs are especially prone to vex gouty persons at night, and sometimes precede a severe attack for several nights. The special determinations of gout to certain parts are inseparably connected with excess of uric acid in such parts, and thus we may fairly conceive that some of the nervous symptoms which occur in the gouty owe their cause of irritation of nervous tissue to this peccant matter. Insomnia may well be one symptom due to this irritation.

The particular insomnia described is rather the indication of the gouty habit than a special phase of either acute or chronic gout, as commonly understood, and as such, its importance has not hitherto been clearly signalized. Its recognition is necessary for the employment of the only line of treatment that can truly avail to avert it, and to break the persistence of the habit on which it depends. Hypnotic agents constitute improper means of relief in such cases. The gouty taint must be combated. Strict attention to diet, a free dilution of the blood with bland fluids, regulated exercise of both mental and bodily faculties, together with occasional mercurial purgatives, will commonly avail to overcome the misdirected tendencies and to secure good nights for sufferers from these unpleasant affections.

On the Use of a Feebly Alkaline Water as a Vehicle for the Administration of the Iodide and Bromide of Potassium, etc.—Dr. E. C. Seguin (*Archives of Medicine*, August, 1881) thinks he has found the means of administering the iodide of potassium and the various alkaline bromides in a harmless way (as regards the digestive organs). He has for several years employed a solution of iodide of potassium made by dissolving the salt in water. Experimenting upon a considerable bulk, it has been found that there is a loss by volume of one-fifth in mixing the salt and water in equal parts by weight. In other words, a drop of this solution contains about ⅛ of a grain, or .05. A patient who takes a dose of one hundred drops of this solution does not, in reality, receive (as is often erroneously stated) one hundred grains, or 6.0, of the salt, but only about eighty grains, or 5.0. This difference is of considerable importance in the treatment of cases requiring the maximum doses of iodide. Of this solution Dr. Seguin directs that a definite number of drops be given in a liberal quantity of Vichy water. For patients living where the syphons of Vichy cannot be procured, or for patients who travel much, a teaspoonful of the effervescent Vichy salts, dissolved in a glassful of cold water, is administered. In the case of patients who cannot afford to buy these preparations, he recommends that a good-sized pinch of bicarbonate of sodium be added to a glass of water. The advantages which he claims for this method of giving bromides and iodides, in weak alkaline waters surcharged with carbonic acid, are twofold: first, the supposed irritating effect of the salts upon the gastric mucous membrane is reduced to a minimum, if not absolutely neutralized. He states that no gastric or gastro-intestinal disorder has been observed while giving full or even very large doses of the salts to patients of various ages. As much as sixty to one hundred grains of the bromides have been administered in a day; and even when bromism occurred, the gastric symptoms were almost nil. The iodide of potassium he has thus given in doses varying from small doses to ʒ j. or 32.0 in the day, without indigestion. Second, the taste of the bromides and iodides is considerably masked by the sparkle and subacid taste of the effervescent drink.

The idea of giving the iodides and bromides on an empty stomach, although not new, is in opposition to what he thinks is the general practice. Influenced by the (delusive) notion that iodides and bromides produce gastric irritation, most practitioners give them after eating, when they probably undergo more rapid decomposition, and interfere with the process of digestion. Deposited into an empty stomach, which, in normal conditions, presents a neutral or alkaline reaction, more especially if guarded by an alkaline liquid, it is a practical reality that these salts are very efficacious, and that they cause no gastric irritation. Theoretically, it is almost demonstrable that they are absorbed quickly, fully, and with little, if any, change. The contact of the solution may act as a solid body or a portion of aliment, and cause an outpouring of acid gastric juice; this is, however, not proven, and if such an event does occur, the acidity thus produced will be antagonized by the alkaline salts of the solution.

An Amusing Diagnosis.—The following was obtained from a clairvoyant, and sent to us by a correspondent:

"This lady has a slight congestion of womb and ligaments, attended with neuralgia, which, from a reflex action and sympathetic condition, affects the brain. The liver has malarial symptoms, affecting the stomach and system generally or constitutionally, and causing an impoverishment of the blood and nervous irritation. The condition of the system at present requires local healing and astringing treatment for the uterus, and tonic anti-malarial remedies for the general depletion of the system."

## IS GUITEAU INSANE?

THE coming trial of Guiteau for the assassination of the late President, has called up a question of great medico-legal interest. The principal line of defence to be adopted is, that the assassin is insane. There is no doubt that the American people, with but few exceptions, believe him sane enough to be hanged, and demand his execution. On the other hand, there are unquestionably many strong reasons for believing Guiteau to be of unsound mind. It would be unjust, wrong, and, politically speaking, futile to execute Guiteau if he is insane, even though his victim was the head of a nation. For responsibility is set aside by mental disease, and, furthermore, it has been shown with tolerable certainty, that the fear of execution has no deterrent effect upon the criminal impulses of the weak-minded and insane.

So that the question of Guiteau's mental condition and responsibility is one that deserves a most serious consideration.

It is claimed that Guiteau is a monomaniac. He has that form of monomania which has been described by German writers as *primäre Verrücktheit*, and by others as partial intellectual insanity. It is a disease in which deluded opinion forms the striking feature, though delusion is not always present, while there may be with it some perversions of the emotions, or some illusions, simple or transformed. Writing of the general mental condition of this class, Spitzka (*St. Louis Clinical Record*, Dec., 1880) says: "The general intellectual status of these patients, though rarely of very high order, is moderately fair. A monomaniac is frequently crochety, irritable and depressed. He concludes that he is a personage of some importance. Some great political movement takes place, he throws himself into it, either in a fixed character that he has already constructed for himself, or with the vague idea that he is an influential personage. He seeks interviews, holds actual conversations with the big men of the day, accepts the common courtesy shown him by those in office as a tribute to his value, is rejected, however, and then judges himself to be the victim of jealousy or of rival cabals, makes intemperate and querulent complaints to higher officials, perhaps makes violent attacks on them."

This description shows very well what are some of the occasional phases of monomania. And this description, though written in 1880, corresponds curiously with the actions of Guiteau. It must be remembered, however, that actions almost similar may be performed by perfectly sane men. They do not prove insanity, but are simply liable to form a part of the clinical picture of one form of that disease.

The evidences of Guiteau's unsound mental condition are, so far as the facts of his history are yet given, as follows: there is evidence of hereditary taint, an uncle and two cousins having been insane. Guiteau was carefully brought up and well educated, but early showed an unbalanced mind. When quite young he joined the Oneida Community. Here his conduct was so peculiar that he was, after a time, obliged to leave. His actions showed moral perversities and disagreeable personal traits rather than any notable intellectual aberrations. Still he was remembered on account of his intense conceit, his eccentricity, and occasional incoherence.

After leaving the community, he studied and practised law, but never rose above the position of a bill-collector. Somewhat later, in writing to his relatives, he assumed the title of "Hon.," and continued to use it, despite expostulation. Although without credit or friends, he formed a scheme for buying out the *Chicago Tribune*, which paper he expected that he could then conduct. His intense and morbid egotism was constantly displaying itself. It took the form of a craving for notoriety, which at times developed with considerable force. He attempted the *rôle* of a lecturer and failed. His lectures contained a seeming delusion, which was defended with incoherence. This delusion was that the second coming of Christ took place A.D. 70, at the time of the burning of the Temple. In advertising his lecture, he had himself announced as a celebrated Chicago lawyer. He delivered one political lecture before a colored audience during the last Presidential campaign. This seems to have been the sole service that he performed. Upon it he built up his belief that he was entitled to the Austrian Ministry, and, that failing, to the Paris Consulship.

The frame of mind in which he conceived the project of murdering the President does not seem to have been one of malice. He acted under a deluded opinion that the deed was for the good of the Republican party and the nation. This delusion was excited and fed, no doubt, by his extreme egotism and craving for public attention. The purpose

of assassination once formed, there was no doubting or thought of change afterward. The preparations for the murder were made deliberately, and the after-consequences were, in a degree, considered. Since the murder, Guiteau has shown no evidence of remorse, but there has developed an intense solicitude for his personal safety. He has shown great insensibility to the suffering he has caused, and has appeared rather proud of the sickening distinction he has achieved.

The above are the principal facts as yet furnished which contribute to the belief in the assassin's insanity. It must be added that the general character of the man has been extremely bad. Besides being vain and pretentious, he has always appeared quite insensible to shame, and has never hesitated to importune aggressively for any desired favor. He was utterly unreliable, lied, evaded his debts, earned money by the worst methods of the shyster lawyer, was brutal to his wife, and immoral in his habits. His manner was mean and cringing. His intellectual ability is, perhaps, a little below the average.

With these, and other facts that are quite generally known, we may be able to form some idea as to which side of the border-line between sanity and insanity Guiteau is to be placed. Of the factors of an unsound mind, we can find in Guiteau's mental history more or less evidence of delusion, incoherence, and of moral perversion. The morbid egotism, the homicidal act, performed without malice, and the subsequent development of a morbid fear of death, should also be taken into account. A more complete history of the assassin's life might bring out other factors. But, at present, it is chiefly the evidence of a tendency to deluded opinions proceeding oftenest from a morbid egotism, that must furnish the test of his intellectual condition.

Judged by this test, we cannot convince ourselves that Guiteau should be considered positively insane. He is on the border-line where the eccentricity of weak minds trends upon insanity. Crichton Brown described a class of persons who stand half way between the insane and idiotic on the one hand, and the simply "nervous" on the other. They constitute the "crazy circle." Guiteau has all his life belonged to this class. It will be claimed that in his last murderous act he showed himself to be unmistakably insane. We do not think that there is yet evidence enough to prove this.

It must not be forgotten, as Bucknill and Tuke have said, that deluded opinion upon one subject, standing by itself, and without hallucination or perversion of the emotions or instincts, can rarely be recognized as a form of insanity. The delusions of Guiteau were not accompanied by such perversions to any marked degree. It is worthy of note that, despite his eccentricities, the uniform story is that nobody thought him insane. Indeed, the delusions of Guiteau, including his last, can hardly be called such if we adopt the strict language of some authors (Guy) who define a delusion as an involuntary belief without data or premise. The delusion of Guiteau regarding his crime, which had some data, is most widely marked off from that of the genuine monomaniac who, for example, believes himself the Holy Ghost; and none of his previous quasi-delusions had indicated to acquaintances anything more than a disagreeably eccentric character.

As regards the morbid egotism which formed a part of Guiteau's character and so often shaped his actions, this is indeed a common symptom in the insane and in the unbalanced mental condition that precedes insanity.

But neither morbid egotism nor consequent delusions necessarily stamp the individual as a lunatic. The degree of the one, the irrationality of the other, as well as accompanying facts, must be considered. Guiteau's egotism was great, but not phenomenal; his delusions were contemptible, but not entirely without data. Add to this that his feelings, though brutal, were not uncontrollable; that he was more vicious than passionate; more coherent in his deceits than incoherent in his language or writing, and we get the picture of a man who is vain, brutish, weak-minded, and offensively eccentric—but not insane.

Even supposing, however, that some taint of insanity were upon this man, it would yet remain to be proved that he was not legally responsible for his deed. It is now a recognized principle that a man may be insane in some particulars, yet sane and capable of legal and responsible acts in other directions. If a man has the delusion that a person whom he meets has done him an injury, and, acting on the delusion, kills this person, he is responsible in law. This may not be the correct test of responsibility, but it is, we believe, the one still generally held, and is the one endorsed by Elwell in his recent treatise on medical jurisprudence.

Now, in the case of the present murder it may be shown that the act was done under a kind of delusion; but this will not be enough. It must be further shown that the delusion was such that Guiteau did not know the nature of the act he was doing; or, in other words, he did not know he was doing wrong. We suspect that this will not be an easy thing to demonstrate. Though the assassin claims that his act was for the party's good, he has never shown any evidence that he did not understand its immorality and heinousness.

It may be that the evidence will develop facts which will put Guiteau's mental condition in a different light. But now it appears quite clear that the prisoner's crime was the act of a vicious nature,

congenitally bad and erratic, perhaps, but made worse by self-indulgence and the unchecked promptings of a supreme egotism. So far as their natural infirmities go, such men deserve pity, but they cannot be considered irresponsible. And, if society must protect itself by taking a life for a life, it must in justice bring to account such miscreants as Guiteau.

---

THE PROGRESS OF PERITONEAL SURGERY.

RARELY, even before the New York Academy of Medicine, is a subject brought up for discussion which commands so much interest and affords so much practical instruction as that treated of in the paper of Dr. Sims. In another place we publish a full abstract of the remarks of our distinguished countryman, and also the comments and criticisms of other gentlemen who took part in the proceedings of the evening. The subject is one which, of late, has claimed the attention of the leading surgeons throughout the world, and its careful study has invited the performance of operations in abdominal surgery which have been daring, brilliant, and, in a goodly number of cases, successful. While, however, there is danger that enthusiasm for bold and startling operations upon the peritoneal cavity may be carried to extremes, it is safe to say that, by a more thorough mastery of the principles which underlie success, even in the most daring surgical procedures upon the abdomen, much substantial progress is to be made. The time has not come when we can distinctly draw the line between what can and what cannot be done in operating upon the peritoneum and the organs covered by it; but we are cautiously and surely drifting in the right direction. The surgical opinions, pro and con, regarding the practicability of these operations, are very clearly and satisfactorily brought out in the paper and discussion to which we now refer. The author of the paper, with the foresight and prerogative of an acknowledged leader in his specialty, prospects possibilities and anticipates results which are salient points for profitable discussion; at the same time they challenge, in a direct and practical manner, the calm and stern judgment of the clinical experience of surgeons generally.

From his standpoint it is safe to assert that Dr. Sims cannot go too far in his advocacy of the utility of abdominal sections for all possible injuries or diseases connected with the peritoneal cavity. But it is fortunate, however, that the profession at large is not yet prepared to accept his advice *in toto*. It was certainly becoming in him to claim ovariotomy as the parent of peritoneal surgery; but there are certain conditions in the performance of that operation which, unfortunately for general surgery, never obtain in certain emergencies when the surgeon may be tempted to cut into the abdominal cavity. It is not fair to compare the two conditions. As was well said by Dr. James R. Wood, in the course of his timely and practical remarks, patients for ovariotomy have a special preparation for weeks, while those with injuries of the abdomen, who seem to require immediate relief by operation, are in a condition of shock at the time. Obviously, the addition of the extra shock of an operation would, under the circumstances, inevitably strike the balance on the wrong side. Here at least a distinction can be easily made between an operation which is practical and consequently successful, and one which is impracticable and consequently dangerous. The difficulty of diagnosis in cases of injury of the abdominal cavity is one not sufficiently insisted upon by the advocates of these daring operations. There are so many possible accessory conditions to be taken into account in regard to the organ wounded, the degree and source of hemorrhage, and, in case of gunshot injury, the exact locality of the missile, that the surgeon is apt to hesitate in operating, and inclined to shrink from a responsibility of directly inviting a fatal issue. Until we can be sure on all these points, we can never be warranted in doing more than treat the patient on general principles.

We are somewhat surprised to learn that septicæmia is the chief cause of death after ovariotomy. While admitting that fluids in the cavity of the peritoneum may be rapidly absorbed, we are at a loss to understand how simple bloody serum could so soon become septic as to make it difficult to separate its results from the usual ones of shock after an operation. It is hard to believe, within as short a time after an operation as is possible for bloody serum to remain as such, that the poisoning of the system should be profound enough to produce death. But we are inclined to think that the distinguished author of the paper is theorizing on this point, rather than drawing from his experience in the dead-house. There is something in his earnest advocacy of drainage that offsets in a somewhat striking manner the benefits of the much-vaunted antiseptic system. When of the two methods—drainage and disinfection—it is said that drainage ranks first, the keynote is struck for all the real successes that have been directly obtained by wound-management in peritoneal surgery. Clinical experience has proved this over and over again. Through-drainage also takes an equally high rank as a method of procedure in every part of the body subject to disease or injury, but the opportunities for emphasizing the fact should never be lost. If for general surgery the paper has done nothing more than enforce anew the importance of through-drainage, and bring it prominently forward as a main reliance in otherwise desperate and unpromising cases, the author has conferred a lasting obligation on his brethren.

THE DISCHARGE FROM PRESIDENT GARFIELD'S EAR.

THE letter of a correspondent in another column, referring to the probable cause of discharge from the external auditory canal of the late President Garfield, brings to the surface of discussion some interesting points in connection with metastatic parotitis. The grounds for supposing that the inflammatory processes in the parotid developed otitis media, and that the discharge from the external meatus was in reality due to ear disease, are ingeniously substantiated by his analysis of the symptoms presented, and by the conditions developed during the latter period of the patient's life. It is well known that parotitis pure and simple, as in ordinary mumps, is frequently followed by inflammation of the middle ear. Whether or no there is a direct connection between cause and effect, through what the correspondent chooses to call nervous sympathy, may be open to some question. It is by no means impossible to suppose that such is not the case, as the communications of the nervous supply of the parotid with that of the middle ear is quite direct through the inosculations of the auriculo-temporal nerve and the branches of the carotid plexus. There appears, however, to be good reason for supposing that the inflammation of the middle ear may be the result of ordinary metastasis through the vessels and lymphatics which are common to both localities. Indeed, it is asserted by competent authority that this course is the most likely one for the extension of inflammation from the parotid to the tympanic cavity and the contiguous parts. Such at least has been an accepted explanation by Vogel and others, for the extension of disease from the gland in question to the labyrinth in the cases of sudden and complete deafness which sometimes accompanies ordinary mumps.

It is not improbable that the discharge of pus from the external meatus was made through an opening into the cartilaginous floor of the external auditory canal, as the pus might have taken such a route by burrowing underneath the tough parotido-masseteric fascia. This is, however, quite an uncommon occurrence, and we doubt if otologists generally would accept it as a reasonable explanation, either on anatomical or pathological grounds. On the other hand, a sudden and profuse discharge from the ear, accompanied by an immediate relief of pain and subsidence of the pulse, are phenomena which are often enough associated with rupture of the drum-head, and liberation of pent-up pus in the tympanic cavity, to warrant serious consideration in studying the relations of cause and effect in this particular case.

The most significant symptom as pointing to middle-ear trouble is, without doubt, the occurrence of facial paralysis. This latter condition is most apt to ensue as the result of the involvement of the seventh nerve as it passes through the Fallopian canal. This is one of the most frequent explanations for Bell's paralysis, aside from direct wounds to the nerve, or occasional stretching of its trunk. But the only way at present to clear up doubts on the subject is the declaration from the gentlemen who made the autopsy as to whether or no any opening was found through the cartilaginous portion of the canal. No mention is made of this fact in the official account of the autopsy; but this is possibly an accidental omission.

# Reports of Societies.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, October* 6, 1881.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Corresponding Secretary, Dr. John G. Adams, announced the death of Dr. James P. White, of Buffalo, N. Y., Honorary and Corresponding Fellow of the Academy, and appropriate and eloquent remarks, paying a high tribute of respect to the memory of the deceased, were made by Dr. Austin Flint, who also offered a series of resolutions, which were unanimously adopted.

Drs. M. Declarc, of Paris; Leopold Meyer, of Copenhagen; J. J. Gelbke, of Dresden; Major Gardner, U.S.A.; H. D. Didama, of Syracuse; Sabal, of Florida; Newell, of New Brunswick, N. J.; Shine, of St. Augustine, Fla.; Cushing, of San Francisco, and Mussey, of Cincinnati, were introduced to the Academy and invited to seats upon the platform.

The report of the delegates to the International Medical Congress was made by Dr. John G. Adams.

THE RECENT PROGRESS OF PERITONEAL SURGERY.

DR. J. MARION SIMS read a paper on the above subject, and had been prompted to do so by what he saw and heard in the surgical and obstetrical sections at the International Medical Congress. His object was to lay before the Academy a synopsis of the recent progress of peritoneal surgery, as reflected at the Congress, and to answer the question, "Does it lead to a better treatment of gunshot and other wounds of the abdominal cavity?"

McDowell, justly styled "the father of ovariotomy," operated as well and with as great a measure of success as did Peaslee, Atlee, or Spencer Wells up to within the last ten years. The later marvellous success of the operation, and the principles of ovariotomy, however, did not belong to it alone, but were applicable to all the organs and contents of the cavity of the abdomen. Ovariotomy was the parent of peritoneal surgery, and the governing principles of the one must govern all operations affecting the other. Peritoneal surgery was a new creation, or discovery, a new domain which had been opened to the profession at large by a few pioneers, who, as in the physical world, "go before and blaze the way for us to follow and take possession." No greater progress had been made in any department of medicine than had recently been made in peritoneal surgery. It had for its foundation the following principles:

*First.*—All hemorrhage must be arrested. This

was not more important in abdominal than in any other branch of surgery, and might be accomplished by pressure, the ligature, or the pressure forceps, which were of comparatively recent date, and were used to arrest hemorrhage temporarily. After the operation was finished they were replaced by ligatures. They were of very great service in ovariotomy.

*Second.*—Clean out the peritoneal cavity thoroughly, as our great master, Thomas Keith, has taught us long ago.

*Third.*—The abdominal incision in the middle line must be properly closed.

The divided edges of the peritoneum should be united. There were the best of clinical reasons for that, as well as the evidence afforded by experiments. If the cut edges of the peritoneum were not included in the sutures, there was necessarily left a raw surface of greater or less length and varying width. Nature protected the peritoneum from such a raw surface by immediate union with subjacent parts, and if the adhesion was with the intestines, serious and even fatal results might follow. Such a result had occurred, and therefore the possibility of its occurrence should be guarded against.

Occasionally the peritoneum unites, while the abdominal parietes gape widely open—a clinical fact which aided in proving the importance of bringing the divided edges together.

*Fourth.*—Drainage or no drainage. In general surgery no one dared to dispute its value. Listerism and drainage became fashionable at about the same time; but to Chassaignac should be given the credit of having brought prominently before the profession the drainage-tube. In all abdominal surgery Dr. Sims preferred complete drainage to antiseptics, if only one could be adopted. The glass tube did no harm; if there was no bloody serum to be drawn off, it could be removed within a few hours, if bloody serum was in the peritoneal cavity, it should be evacuated. Spencer Wells and Thornton rejected the drainage-tube, on the theory that Listerism rendered the peritoneal effusion aseptic, and therefore its absorption was not attended with danger. But Dr. Sims was positive that it was not so in every instance, and, as an illustration cited one of Mr. Wells' cases, in which he assisted at the operation. Much hemorrhage occurred; Dr. Sims suggested the use of a drainage-tube; Mr. Wells regarded the tube as unnecessary, and closed the abdominal incision completely. Symptoms of septicæmia developed; bloody serum appeared in the incision; the wound was opened; pus and bloody serum were liberated; the peritoneal cavity was cleansed and kept clean; the symptoms of septicæmia disappeared, and the patient recovered.

The only valid objection to the drainage-tube was not in its immediate danger, but in its ultimate tendency to favor the development of ventral hernia—a tendency which we must learn to obviate. That is a problem which can be worked out; but he believed that it was better to risk the occurrence of ventral hernia than to take the risk of losing the life of the patient.

The clamp, in ovariotomy, was no longer used in England; it and Listerism were antagonistic.

Dr. Sims then reviewed the operations which must be performed in accordance with the principles governing peritoneal surgery, such as extirpation of the uterus for fibroids, Battey's operation, which Lawson Tait had performed seventy times, with only six deaths, and Savage thirty times without a single death; extirpation of the spleen, extirpation of the kidneys, for which there was a future by way of the abdominal incision, etc.

Lawson Tait had already operated upon a case of hydronephrosis by the abdominal incision, stitched the walls of the cyst to the edges of the abdominal wound, and introduced a drainage-tube. In 1878 Dr. Sims operated for dropsy of the gall-bladder by opening the abdominal cavity, opening the gall-bladder, and discharging its contents, stitching the edges of the wound in the gall-bladder to the edges of the abdominal wound, and, although the patient died, autopsy showed that death was not the result of the operation. Lawson Tait operated upon a similar case in 1880, and his patient recovered. Tait had also operated six times for hydatids of the liver.

Dr. Thomas had boldly opened the bladder in a case in which it was firmly attached to the anterior surface of an ovarian tumor, brought the edges of the opening into the lips of the abdominal incision, and secured them with sutures, and the patient recovered.

With reference to Billroth's operation for removal of cancer of the pyloric extremity of the stomach, we could admire the heroism of the surgeon and the brilliancy of the operation, while we deplored its uselessness.

Laparotomy in obstruction of the bowels had become an accepted operation, and was another triumph following in the wake of ovariotomy.

Hemorrhage from rupture of a blood-vessel in Fallopian pregnancy was an accident which demanded the opening of the abdominal cavity and securing the bleeding vessel. It was Stephen Rogers, of New York, who was the first to proclaim to the world (1867) that it was our duty to open the peritoneal cavity at once in such cases, and secure the bleeding vessel.

Nearly all the operations thus referred to, except ovariotomy, are the result of the progress made within the last ten years, and the principles of peritoneal surgery were now so well established, and practised so successfully, that further triumphs would be achieved.

In 1863 Dr. Sims performed ovariotomy with Nelaton; the patient died, and at the autopsy only bloody serum was found in the peritoneal cavity. In 1872 he published a paper in which he maintained that septicæmia, and not peritonitis, was the great outlet of life after ovariotomy. Dr. Sims then gave a description of the case of Richardson, who received a gun-shot wound of the abdomen in the *Tribune* office, in New York. The patient lingered for several days. Bloody serum was found in the abdominal cavity at the autopsy. It was possible that the patient's life might have been saved by a timely operation. He also referred to the case of James Fisk, in whose abdominal cavity bloody serum was found at autopsy. Extended reference was made to his experience at Sedan, in Prussia, where he found that soldiers dying from wounds in the abdomen had bloody serum in the peritoneal cavity, without trace of peritonitis, thus leading him to the conclusion that they died of septicæmia and shock.

Wounds of the peritoneum, however made, had a common course to run and were all amenable to the same general laws. Should the triumphs of modern surgery be monopolized by ovariotomists? His answer was No. Death from gun-shot wounds occurred from shock, hemorrhage, and septicæmia, but rarely from peritonitis.

Special reference was made to seven cases of gun-shot wounds through the pelvis which he saw at Sedan. All the patients recovered. To these were added one case seen by Dr. Pallen, and four by Major Gardiner, U.S.A.; twelve in all and no deaths.

In the Crimean war, 92 per cent. of the soldiers with gun-shot wounds of the abdomen died. Why do men recover from perforating wounds in the pelvic cavity, and die from wounds in the abdominal cavity? In the one case there is natural drainage for septicæmic fluids along the track of the ball, while in the other drainage is impossible, the fluid falls into the abdominal cavity and the patient quickly dies from blood-poisoning.

Special reference was made to a case of gun-shot wound of the abdomen, in which there was perforation of the intestine, and in which Dr. Newell, of New Brunswick, N. J., thirty-four years ago, made an abdominal incision, sutured the intestines, cleansed the cavity, closed the wound, and the patient recovered.

Dr. Sims also alluded to Dr. Hunter McGuire's address before the American Medical Association at its last annual meeting, as a paper in which advanced views concerning the treatment of gun-shot wounds of the abdomen were advocated.

To his cablegram from Paris, when President Garfield was shot, Dr. Sims made special reference, and stated that it was based upon the supposition, as was then generally accepted, that the abdominal cavity had been penetrated and that hemorrhage into it had occurred. His language then was: "If the President had recovered from shock, and if there was evidence that the ball had traversed the abdominal cavity and severed a vessel which remained a source of hemorrhage, or had perforated the intestines, the only safety was in opening the abdomen, securing the bleeding vessel, suturing the intestines, cleansing the cavity, and treating the case as one of ovariotomy." And he was of the same opinion still. There was no more danger of a man dying from a gun-shot wound of the abdomen, if properly treated, than there was of a woman dying after ovariotomy, if properly performed.

Dr. Sims' conclusions were as follows:

*First.*—Wounds of the peritoneal cavity, however made, have a common course to run.

*Second.*—They have a common termination, and that is death by septicæmia.

*Third.*—This is the general law in death after ovariotomy.

*Fourth.*—It is the general law in death after gun-shot and other wounds of the abdominal cavity.

*Fifth.*—The septicæmia is the result of absorption of bloody serum found in the peritoneal cavity after wounds or operations.

*Sixth.*—Gun-shot wounds of the pelvic cavity are recovered from, because of natural drainage afforded by the track of the ball.

*Seventh.*—Patients with gun-shot wounds of the abdomen die of septicæmia, because there is no natural drainage, and the bloody serum falls into the peritoneal cavity and is there absorbed.

*Eighth.*—The effect of bloody fluid upon the abdominal cavity is such as to demand abdominal incision, the suturing of wounded intestines, the tying of bleeding vessels, the cleansing of the cavity, and the use of the drainage-tube or not, according to circumstances.

*Ninth.*—If this operation be well done, there is hardly any need of a drainage-tube.

The paper being before the Academy, the President invited Dr. Lewis A. Sayre to open the discussion. After complimenting the author on the production of so valuable a paper, he referred to pelvic and abdominal wounds, and asked, Why did the patients with pelvic wounds, to whom Dr. Sims had referred, get well? It was because the wound was through and through, and drainage was established; whereas in the abominal wounds there was no drainage. If, therefore, he was to be shot, he would pray God that the man might have powder enough to send the ball clear through, as the most important item in treatment of such wounds was drainage, *drainage*, and the use of antiseptics might follow as thoroughly as possible. To use a practical illustration: if the bung of a cider-barrel was knocked out, the cider would overflow and foam, but the barrel would never be emptied until the barrel was rolled over and the bunghole brought to the under side, so that complete drainage could take place.

In the first place, however, in all these wounds, as well as in all other conditions, there was a demand for accuracy in diagnosis; and upon that only could true principles of treatment be based.

Col. McKee, M.D., U.S.A., referred to a case in which a soldier in the battle of the Wilderness was shot in the abdomen, and a short time afterward the ball passed by stool, and the man recovered without accident.

He also referred to a case in which a man swallowed a piece of wire and he operated and removed it from the abdominal cavity. (See Medical Record, vol. xv., p. 607.)

Dr. Mussey, of Cincinnati: "What can he say who cometh after the king?" He then gave an account of an abdominal wound inflicted on a woman by a bull, who gored her so that her bowels fell out upon the ground. She gathered them up in her apron, went into the house, and sent for a doctor. She recovered entirely.

Dr. Clinton Cushing, of San Francisco, referred to his cases of epithelioma of the uterus, in which he completely removed that organ through the vagina. He had performed the operation and seen it performed in four cases, and it seemed to him to be justifiable when the surrounding tissues were not involved, and the uterus was entirely movable.

Dr. James R. Wood: I dislike to speak after the king. I do not like to take issue with him. He has spoken as a surgeon who has had to do with the female organs of generation, and others in that region of the body, and which he has treated so wonderfully well. But I am loth to endorse all that my dear friend Dr. Sims has said. I think that the surgeon should be careful how he invades the peritoneal cavity, unless, as my friend Dr. Sayre has said, he has made out an accurate diagnosis, and to do this, especially in gun-shot wounds of this cavity, is almost impossible. I have, during my professional life, seen a great many gun-shot wounds of the abdomen, of the pelvis, of the thorax, all the great cavities of the body, and early in my professional days, I searched for bullets as I should not have done. It is well-known that the slightest obstruction to the passage of a ball, which, unobstructed, would have passed completely through, may deflect it, so that it will lodge in an unexpected locality and at a great distance from the point of entrance. I shall not refer to the case of our beloved President, but I will recall the history of one much like it, which I met in this city some years ago, where a bullet entered upon the right side of the body and passed, as it was supposed, through into the lumbar

region on the opposite side. A surgeon saw this case, introduced his finger at the point of entrance, and reached the liver. He was sure he felt the liver. That man died of blood-poisoning. At the autopsy the ball was found imbedded in the glutei muscles. It had not reached the liver; but had been deflected and lodged in its hiding-place among the muscles of the buttock.

With reference to reaching into the cavity of the peritoneum in search for bullets or injured parts, it is a very serious matter. The fluid upon which Dr. Sims has placed so much stress is not always bloody serum; but very frequently there is a considerable quantity of blood in the peritoneal cavity, and the true pelvis is frequently filled with blood, and the man who makes the post-mortem will fail, perhaps, to find it. I have known that to be the case repeatedly.

Well, suppose the liver is injured, as that organ has been talked about very much lately. Bullets have been felt in it, skilled microscopists have looked for bile or liver debris in the pus, and it is believed that the liver has been wounded. If the diagnosis has been made out, my friend, Dr. Sims, would feel justified in opening the peritoneal cavity for the purpose of securing bleeding vessels and sponging out the blood. But suppose the thicker portion of the liver is wounded, the hemorrhage will continue and it cannot be arrested. The blood-vessels of this organ will remain open because of their anatomical peculiarity, and the ligature cannot be used. These patients usually die within six or eight hours. If only the thin bevelled portion of the liver is injured, the hemorrhage may be slight and may be arrested spontaneously. But suppose we cut into the cavity of the peritoneum and we find blood there in large quantity. The patient is still laboring under shock; for, in penetrating wounds of all serous cavities, especially gun-shot wounds, the shock which follows lasts for a long time. In the celebrated case of Fisk the patient never came out from the shock. But suppose we cut into the cavity of the peritoneum while the man is suffering from shock. What becomes of him? He dies, and probably will do so while we are cleansing the cavity. I am simply stating surgical facts, and we must look them squarely in the face. We have, besides, to look to the reputation of the surgeon, and to the reputation of the profession of which we are members. If the patient dies while the surgeon is operating, and blood is found flowing freely, what will be the effect produced upon the community? Again, suppose that the stomach is perforated, and we proceed to cut out the lacerated portion as Billroth did the diseased portion in cancer of the pylorus—which in my opinion is a dreadful operation to perform. We will sew up the opening, but the contents will escape into the peritoneal cavity and reach down into the pelvis, and if now we make a free incision in the abdominal walls for the purpose of cleansing this cavity, I believe we should get ourselves into trouble. Most of these patients die in shock, they do not live long enough to get blood-poisoning. But we are told that we must not wait, that we must operate at once, lest this bloody serum which reaches the peritoneal cavity gives rise to septic poisoning. Yet we sew up the opening in the stomach, close the cavity of the peritoneum, the patient does not come out of the shock and dies.

The circumstances under which Dr. Sims performs ovariotomy and various other operations are different from those under which the general surgeon is called to treat gun-shot wounds of the peritoneal cavity. The woman upon whom he operates has been prepared for the operation; her condition is as good as it can be made, and there is no shock. The shock in his cases comes afterward; but the general surgeon comes to his patient and finds shock staring him in the face.

While I should be extremely cautious about opening the peritoneal cavity, if I found that this cavity had been penetrated I should keep the entrance patent.

Next with reference to the bladder. I have seen many cases of gun-shot wounds of that organ. I removed in one case a bullet from the bladder. The man had been shot in the right flank; the ball had reached the bladder, and urine was escaping from the external wound. I enlarged that opening, and then, to secure drainage, so highly recommended, I performed the operation for lateral lithotomy, and placed my drainage-tube, which consisted of a soft catheter, into the bladder, carried it out through the flank, and my patient got well.

I had a case in which the patient had been wounded with a knife above the pubes, and below the reflection of the peritoneum over the bladder, which had been opened. I passed a soft catheter into the bladder, and out through the opening above the pubes, and the patient made a good recovery.

I believe in drainage-tubes, but not to the extent to which they are used by our old teacher Chassaignac.

I have introduced a drainage-tube into the bladder when that organ has been penetrated, and with the peritoneal cavity open. I have sewed up the opening in the bladder, and I included the mucous membrane in my sutures, and then introduced a drainage-tube into the cavity of the pelvis through the lacerated peritoneum, and my patient recovered.

If I live long enough, I shall probably perform an operation in which I shall reach into the ischio-rectal fossa, where there has been injury of the peritoneum, with probable escape of blood into its cavity. I propose to go along the side of the rectum into the ischio-rectal fossa, and so enter the peritoneal cavity, and introduce a drainage-tube. This is good surgery. So you see that it is believed that some of the surgeons here are not altogether behind the times, although the gynecologists are getting all the glory. I do not believe, however, that you, sir (Dr. Sims), get half as much as you deserve. This is a great subject; too great to be exhausted in one evening's discussion. I thank you, sir, for opening our eyes. You have said what I have never before heard, and I thank you and those whom you represent for your able paper, for what you have said, and so well said; but to the gynecologists does not belong all the glory.

Dr. Leonard Weber remarked, concerning perityphlitic abscess, to which Dr. Sims had alluded, that it was usually extra-peritoneal, and did not require any early opening of the abdominal cavity for the purpose of evacuating the accumulated pus. The only cases in which abdominal section could come into consideration were those in which abscess developed in consequence of perforation, especially perforation of the vermiform appendix. Dr. Burchard, in a paper read before the Academy, had proposed to make abdominal section in such cases, tie the appendix, cut off the diseased portion, and introduce a drainage-tube. In all other cases, particularly those in which he had operated, an operation earlier than was performed would not have

offered any advantages, because, unless the abscess was caused by perforation of the appendix, it was outside of the peritoneal cavity.

Dr. Sims, in closing the discussion, thanked the Academy and his friends for their generous attention in listening to his lengthy paper, and would particularly remember his friend Dr. Wood, who had so candidly presented his criticism from the standpoint of a justly eminent general surgeon, and also Dr. McBride, who had kindly yielded the evening in his favor.

The Academy then adjourned.

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting, October* 4, 1881.

Dr. T. A. McBride, President, in the Chair.

Dr. W. A. Hammond read a paper, entitled

### SOME OF THE THERAPEUTICAL USES OF NITRO-GLYCERINE.

The speaker referred to the fact that the preparations of nitro-glycerine are very unreliable. It was important, therefore, that the physician should know what preparation his patients obtained. He thought that the best preparation was that of Boericke & Tafel. The usual dose is one drop of a one per cent. solution given on a lump of sugar. This dose ought, as a rule, to produce a sensation of fulness in the head, or a headache, when first taken.

The continuing dose must be employed: that is, the dose must be increased gradually, otherwise good results can hardly be expected. The speaker was in the habit of prescribing ℥j. t. i. d. for one month, then ℥ij. for a month, then, perhaps, ℥iij., and so continuing, modifying according to symptoms.

In the angiospastic form of *migraine*, Dr. Hammond said that he had seen some very marked effects from nitro-glycerine. It would be contraindicated in the angio-paralytic form. The speaker referred to a case in which the angiospastic form existed on one side and the angio-paralytic form on the other. A very severe case of migraine was described. Previous remedies had done no good. One drop of the nitro-glycerine was given. Pain almost instantly ceased, and in fifteen minutes the patient was up. In five days later a subsequent attack came on, but it was similarly averted. Other attacks being thus stopped, the patient was put on the drug regularly. The dose was doubled, making it two drops t. i. d. for fifteen days. She then took three drops for a few days longer. After this the patient stopped taking the medicine altogether. For nine months she has had no attacks, and it seems probable that the case is relieved. The speaker had used it in fifteen or twenty other cases of migraine, and almost universally with good effects. In the few cases where no good was accomplished, he was inclined to think he had made a wrong diagnosis.

The drug had also been used in *epilepsy*. In the beginning of an epileptic attack there is, as is well known, a spasm of the arterioles; nitro-glycerine prevents this—makes it impossible indeed. It acts similarly to nitrite of amyl, but its effect is more continuous. The speaker had given it for a year, and had gradually increased the dose to thirteen drops in one case. He had sometimes given bromides with it, and they seemed to work very well together. In the status epilepticus, and some other forms of epilepsy, when bromides are not efficient, nitro-glycerine is very effective. The case of a child who had epileptic attacks every other day was related. The disease had lasted two or three years; bromides had done no good. Nitro-glycerine was given, and since then the patient has only had a few attacks. The dose was kept at one drop three times a day. Children can bear drop-doses very well.

The speaker had used nitro-glycerine in twenty or thirty cases, and he believed that in every case it had done some good. In some cases it had stopped them permanently, or so it seemed.

In angina pectoris, or cases which he believed to be such, the nitro-glycerine had been used. In two cases where the drug was given, the attacks did not continue so long as the medicine was taken.

Dr. Lente asked whether if a good preparation was obtained it would keep?

Dr. Hammond said that it would not change if the bottles were kept corked. It was volatile, but underwent no chemical change so far as he knew.

Dr. Lente asked if thirteen drops three times a day was the largest dose Dr. Hammond had given, and was informed that it was. Dr. Lente said that he did not think the bromides and nitro glycerine had any antagonistic action (as Dr. Hammond seemed to think). Dr. Lente thought it the general belief now, that the action of the bromides was not on the circulation but on the nervous tissue itself.

Dr. J. C. Peters said that he was familiar with the action of nitro-glycerine when it was first introduced twenty years ago. He was then treating angiospastic migraine with conium, and the other form with nux vomica. He had used nitro-glycerine by inhalation, using the pure drug (which, it was suggested, must be dangerous). He had not got satisfactory results with nitrite of amyl in angina pectoris. Some illustrative cases were then related.

A Garfield Memorial Hospital.—A project which deserves the highest praise has recently been set on foot in Washington. It is that of erecting a hospital which shall perpetuate the memory of the late President Garfield. The most prominent citizens of Washington have been enlisted in the project, and there seems little doubt of its ultimate success. A meeting definitely organizing the plan was held on October 5th. The following account of its proceedings will show the interest that has been aroused regarding the matter:

The meeting organized by the election of the following officers: Chairman, Mr. Justice Miller; Vice-Chairmen, the Hon. Thomas L. James, the Hon. George B. Loring, the Hon. William Lawrence, Judge William Strong, Judge D. K. Cartter, Commissioner Dent, W. W. Corcoran, Gen. Eppa Hunton, Prof. Spencer Baird, and John W. Thompson; Secretary, John A. Baker; Treasurer, the Hon. James Gilfillan. Justice Miller stated the object of the meeting, and the applause which followed attested much feeling on the subject. The Hon. A. G. Riddle, of Ohio, delivered an eloquent address, and a committee on resolutions was appointed. The Chairman, Mr. A. S. Solomons, soon reported, and recommended the appointment of an executive committee of twenty-five persons to adopt the necessary means to carry out the object of the meeting, which was adopted. It was announced that subscription lists would be prepared by the committee, and that the whole country and foreign nations would be asked to place the memorial hospital on a broad national and international basis of common humanity.

# Correspondence.

## CONCERNING HYPNOTISM.

To the Editor of the Medical Record.

Sir: The letter from Dr. William A. Hammond, which appears in the last issue of your journal, entitled "A Word for Dr. Beard," suggests to my mind some thoughts in connection with the subject of hypnotism, which I hope you will kindly allow me to express through your columns.

Dr. Hammond expresses "surprise and regret" at the criticisms of Dr. Beard's experiments, made before a medical audience at the Waterloo Hotel, in London, by Dr. J. Crichton Browne, and published in the *British Medical Journal* of August 27th.

I wish it understood that in this letter I have no desire to call in question the veracity of either Drs. Beard, Hammond, or their subjects, or to express my opinion of the motives which has prompted these gentlemen to agitate the subject of hypnotism for the past year in this city, but only to state the facts which I have obtained by a careful study of the subject, and to note the observations made at the different public and private exhibitions given by these gentlemen in New York.

It is difficult for me to understand how Dr. Hammond should be so surprised at Dr. Browne's strictures of Dr. Beard after his own experience with these same experiments and "trained subjects" before the New York Medico-Legal Society. At the last April or May meeting of the above society, it was announced that Dr. Hammond would read a paper on the "Medico-Legal Relations of Sygignocism," the latter term having been coined by him to take the place of hypnotism.

After explaining the etymology of the term, he proceeded to give a physiological explanation of the condition of the brain during trance, which was purely hypothetical, and must have originated in his own imagination.

Then, to prove to the society that a person entranced was not legally responsible for his acts, he arranged chairs so that they were to represent a house, in an upper story of which there was a sum of money, and which was to be entered by the basement, a space under the bottom chair representing the basement door. He then pointed his finger at the subject in the usual way and he became at once entranced, and, upon being told by Dr. H. of the presence of the money in this improvised house, the young man crawled under the bottom chair and brought away an imaginary sum of money, which he stupidly tried to hide on the stage, and also denied having stolen any. He later pointed out a man in the audience and directed the subject to murder him, which he attempted to do with a paper dagger or other harmless weapon. Another experiment was to have the subject rest his heels and occiput on the backs of two chairs with the body extended.

At this juncture, Dr. Birdsall, an able young physician of this city, went forward and did the same thing, and when he had let himself to the floor, he simulated the symptoms of trance, and Dr. Hammond announced to the audience that "the man is entranced." Birdsall soon rose to his feet, laughing at the ruse.

To prove that these subjects were anæsthetised, he pricked them with needles, and to show the absurdity of such a test, I myself went forward and allowed Dr. H. to lock a pair of bull-dog forceps on the lobe of my left ear, and I am prepared to offer to Drs. Hammond or Beard that, with one month's notice, I will agree to go through with all the experiments they have done on their trained subjects, without pretending to be in other than my normal condition.

Another meeting was appointed by the society for further discussion of the subject, at which Dr. Hammond was conspicuous by his absence.

This discourse of Dr. Hammond's, with the discussion, has not been publishedin the "Bulletin" of the society.

I have witnessed many other public and private exhibitions of these "trained subjects," and they have all been alike absurd.

As Dr. H., in his letter, has used the word "insult" in connection with Dr. Browne's statements, I will also use it, and state that I consider it an insult to an intelligent audience to offer such evidence in proof of the existence of a state called trance.

John H. Girdner.

45 West Thirty-first Street, N. Y.

## THE DISCHARGE FROM THE LATE PRESIDENT'S EAR.

Did it arise from the Suppurative Process in the Parotid Gland, or from Otitis Media Purulenta?

To the Editor of the Medical Record.

Sir: The writer's attention was drawn, during the President's illness, to the statement made in the official noon-bulletin of August 26th, that "At the morning dressing of the President it was observed that pus from the parotid swelling had found its way spontaneously into his right external auditory meatus, through which it was discharging." This announcement of the establishment of an otorrhœa, without any allusion to the possible existence of previous aural inflammation, induced me to watch the progress of the case with increased interest, and I had hoped, that when the results of the post-mortem and the history of the case had been given to the public, that some further explanation of the phenomenon might be found. Other mention of the aural discharge than that given in the official bulletins having been omitted, the history of this important case remains imperfect unless some light can be thrown on the subject from a study of the history as it has been given. With such an object in view, I therefore beg you will allow me space in your columns for a brief review of this feature of the case.

It seems that the swelling of the parotid gland was first observed by the surgeons in charge of the case on August 18th (Dr. Bliss's report of the case, Medical Record, October 8th, p. 396), and suppuration was not thought to be impending until the afternoon of August 24th, when an incision into the swelling was followed by the liberation of a small amount of pus. On August 26th, the discharge of pus from the ear alluded to at the beginning of this communication took place; for several nights previous to this event "mental confusion" had existed, but afterward the mental disturbance ceased. Dr. Bliss states in his report above alluded to that "when the climax of suppuration (referring to the parotid gland) was reached, a free discharge of laud-

able pus followed, with a rapid abatement of the more urgent symptoms." Now it will be observed, by referring to the official bulletins, that only a small quantity of pus was evacuated when the first incision was made on August 24th, and that suppuration was at no time reported as "free" until August 28th. Relief seems rather to have followed the discharge from the ear, than the establishment of free suppuration two days later. We have a confirmation of this view of the case not only in the disappearance of the cerebral symptoms, but in the state of the circulation; the pulse, which had been about 108 from the time the parotid swelling was first noticed on August 18th, rapidly ascended from August 24th—the date of the first incision—until August 26th, when it reached 120, where it remained for about twenty-four hours, and then rapidly fell again to about 100 to 108, at which point it remained. The exacerbation in the symptoms observed at this time could, it would seem, be accounted for by the existence of an acute inflammation of the middle-ear, a discharge from which, through rupture of the membrana tympani, was promptly followed by decided relief.

It has been the belief of the writer since first reading the account of the aural discharge, that the inflammation of the parotid gland was the cause of an aural inflammation through nervous sympathy, as is frequently seen in mumps, and that the cerebral phenomena which occurred during the period immediately preceding the purulent discharge from the ear, were owing to the intimate relations that exist between the middle ear and the brain.

The writer, in a very considerable experience in surgical diseases of the ear, has never known of the passage of purulent matter from the region of the parotid gland into the external auditory canal, and, judging from the density of the cartilaginous walls of the canal, it would require a much longer period of time for their perforation than was afforded in this case.

Another evidence of middle ear disease having existed in this case was the occurrence of Bell's palsy during the period under consideration; this symptom, of course, may attend swelling in the parotid region should the facial nerve receive injury from the swelling, but such a result is unusual in the writer's experience, whereas, facial paralysis is *not* uncommon during the course of middle-ear affections, from pressure on the nerve in its course through the Fallopian canal.

As is well known, in the more grave cases of metastatic parotitis, especially when gangrene occurs, the facial nerve may be greatly injured, and cases have been reported where pus has found an exit through the external auditory canal. But in the case before us the swelling of the gland was by no means great, which lessens the probability of pus having forced its way into the external auditory meatus, or of the nerve having been injured by the swelling of the gland.

The writer confesses that his surmises may be erroneous, and, indeed, he can scarcely imagine that a thorough examination of the ear was not made during the time that so much disturbance existed in its immediate neighborhood, for treatment of that most painful affection—otitis media purulenta—in its early stages may greatly relieve the patient's sufferings. * * *

New York, October 18, 1881.

A Hospital at Cornell.—The late Mrs. J. M. Fiske has left $40,000 to establish a hospital at Cornell for the benefit of the students.

## DECREASE OF SIZE OF HEAD.

To the Editor of The Medical Record.

Sir: In a late number of the Record there is a short article, "Science and the Hatters," in which it is said that the discovery has been made that the human head, contrary to the accepted doctrine of evolution, was decreasing in size. For several reasons it is probably more in appearance than in reality. The very extensive substitution of the soft and flexible hat of the present period for the hard, stiff, round, bell-shaped, or stove-pipe hat of a former time enables all who wear the soft hat to use a much smaller number, with equal or superior comfort. In the next place, the frequency of alopesia will account for a great reduction in the size of hats. Baldness was at one time an exception, now it is the rule even with the comparatively young men of the present age. The hard hats are now made in many cases to fit the cast of the head, which will reduce the size considerably. And may not mastication of food, in improved modern cookery, have some effect upon the growth and development of the origin of the masseter muscle? In the next and last place, mental culture will naturally tend to increase the growth and development of the frontal and superior (cerebrum) portion of the brain, at the expense of a corresponding decrease of growth and development in the occipital (cerebellum) portion of the contents of the cranium, thereby reducing the size of the head in the antero-posterior diameter, when there may be an increase in the weight and volume of the same when taken altogether. If in truth there is a real reduction in the size of the human head, aside from what appears to be from the change in hats and baldness, it might be well to give the subject a thorough investigation. But I am clearly of opinion that the decrease is more in appearance than reality.

A. G. Smythe, M.D.

Baldwyn, Miss.

The Work of the Sanitary Inspectors in New York.—Assistant Sanitary Superintendent Janes made a report to the Board of Health October 4th, giving a summary of the work done by the summer visiting corps of physicians. During the five weeks ending August 17th, the whole number of houses visited was 22,627, containing 129,625 families. The whole number of cases treated was 5,185, and 4,954 excursion tickets were distributed. Nearly one-half of the cases found are arranged under the head of diarrhœa, and number 2,488. There were 639 cases of cholera infantum treated. These two diseases were more generally found in the crowded tenement-house districts, while malarial affections, being the next in frequency, were more generally met with in the upper and more sparsely settled districts. Of these affections there were 274 cases, including malarial dysentery. There were also 105 cases of bronchitis, 83 of difficult dentition, and 52 of what was reported as gastric derangement. The contagious diseases met with were as follows: Whooping-cough, 76; measles, 36; diphtheria, 11; and scarlatina, 28.

Statistics of Nephrectomy.—According to Dr. Barker (*Lancet*, April, 1881), the number of cases on record is 54; recoveries 26, deaths 28. In eleven of the cases a wrong diagnosis was made. The lumbar operations show rather better results than those in the linea alba.

# Obituary.

## DR. CHARLES B. WHITE,

SURGEON AND MAJOR U. S. A.

Dr. Charles B. White was born in New York City, September 12, 1837, and was the son of Dr. Ambrose L. White, who practised here for thirty-five years. His alma mater, the College of New York City, conferred on him the degree of A.B. in 1854, A.M. in 1857, and he graduated from the Medical Department of the University of the City of New York in 1859. He then became house physician to Bellevue Hospital, 1860–61, and entered the United States army as assistant surgeon at the commencement of the War of the Rebellion in 1861. His first service was at Fortress Monroe, Va., where he remained until the peninsular campaign, when he obtained field duty. On one occasion he and his horse were enveloped in dust and dirt by a shell, and were supposed to have been killed, but fortunately both came out uninjured.

After the battle of Malvern Hill, it was necessary for several surgeons to remain with the wounded, and volunteers were called for. Dr. White, observing hesitancy, was among the first to offer his services. At this stage of the war no consideration was shown to medical officers, and he consequently became a prisoner.

He returned to the Army of the Potomac, serving in the several actions, till after the battle of Fredericksburg, Va., when he took charge of the General Hospital at Pittsburg, Pa.

He afterward served in the West and Southwest, and was made Acting Medical Purveyor at New Orleans, La., and during an epidemic of yellow fever at Jackson Barracks, he was a volunteer medical attendant.

What was to him an imperative duty was attended with, on this as on many other occasions during his service, great sacrifice. His conscientious ideas of personal responsibility was such, however, as never to deter him from facing either the dangers of the battle-field, the sufferings of prison life, or the ordinary terrors of pestilence.

Dr. White's conduct at Malvern Hill and Jackson Barracks speaks volumes. His subsequent service in the army was respectively at Fort Schuyler, N. Y.; Camp Independence, Cal.; Columbus, Ohio.

His last post was at the latter place. Here commenced the development of an adeno-sarcoma in his left axilla, which eventually caused his death.

His friend, Dr. J. W. S. Gouley removed the growths from his left axilla, September 21, 1878, assisted by Drs. McParlin, U. S. A., W. T. White, Z. E. Lewis, and T. L. White. There was a marked indication of return of the disease toward the close of the past year. Last spring he again presented himself to Dr. Gouley, who, after counsel with other skilled surgeons, in and out of the army, concluded it was unwarrantable to operate.

During the later months of his life he suffered the agonies of martyrdom, consequent upon the involvement of the nervous trunks in his axilla, but quietly, patiently, and resignedly he awaited the hour of his release, and died August 10, 1881, at his residence, Wilton, Conn. His widow, three daughters, and two sons survive him.

The type of an honorable gentleman, of a faithful worker in his profession, and of a consistent Christian, he has left behind him the enviable record of services which, in every sense, were "well done," with a single eye to the performance of the highest duties toward God and man, and he has his reward.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October 9, 1881, to October 15, 1881.*

Magruder, D. L., Major and Surgeon, Medical Director Dept. of the Missouri. Granted leave of absence for one month. S. O. 207, Dept. of the Missouri, October 11, 1881.

Woodhull, A. A., Major and Surgeon. Granted leave of absence for four months. S. O. 227, A. G. O., October 7, 1881.

Jaynett, G. P., Major and Surgeon. Granted leave of absence for one month. S. O. 231, A. G. O., October 12, 1881.

Koerper, E. A., Capt. and Asst. Surgeon. Assigned to duty at Plattsburg Barracks, N. Y., as Post Surgeon. S. O. 180, Dept. of the East, October 7, 1881.

Corson, J. K., Capt. and Asst. Surgeon. Confirms telegraphic instructions of this date, directing him to report to the Com. Officer, Battalion Fourth Artillery, at Fort Yuma, Cal. S. O. 114, Dept. of Arizona, October 5, 1881.

Harvey, P. F., Capt. and Asst. Surgeon. Granted leave of absence for twenty-five days, to take effect on adjournment of the G. C. M., of which he is a member. S. O. 182, Dept. of Dakota, October 5, 1881.

Cowdrey, S. G., Capt. and Asst. Surgeon. Granted leave of absence for four months. S. O. 228, A. G. O., October 8, 1881.

Robinson, S. Q., First Lieut. and Asst. Surgeon. Granted leave of absence for four months. S. O. 228, A. G. O., October 8, 1881.

Dr. John Buchanan Again in Court.—"Dr." John Buchanan, who has just undergone a sentence of ten months in the Eastern Penitentiary, which was imposed upon him by the United States Court for having conspired, with others, to defraud the court out of the amount of his bail, was brought into court in charge of the prison authorities, on a writ of *habeas corpus*, for sentence upon a plea of guilty in the

Quarter Sessions to the charge of issuing bogus diplomas. As his counsel was out of the city, sentence was deferred, and the defendant was given into the charge of the keepers of the county prison.

PROFESSOR VIRCHOW IN POLITICS. — One of the greatest Liberal meetings ever held in Berlin took place on October 6th. It was in support of Virchow's candidature for the Reichstag.

OPIUM-SMOKING IN AMERICA.—Four thousand is a moderate estimate of the total number of native American victims to the opium habit, and these, it is estimated, consume one hundred grains of the drug a day. This gives a daily consumption of four hundred thousand grains, or about nineteen thousand pounds during the year. About three drams of the smoking opium, equivalent to six drams of the crude drug, make the average quota of a day's consumption, and this much costs from fifty to seventy-five cents. Some who go to perpetual excess, however, have been known to consume as much as one and one-fourth pound during a day. Taking the average, however, it will be found that the man who hankers after the deleterious and short-lived enjoyment of the drug can gratify that foolish taste only at an expense of $200 a year, and the combined indulgence of all American opium-smokers will be found to be carried on at a cost of over three-quarters of a million of dollars yearly. And yet this waste is constantly being increased and the ranks of the fools multiplied, notwithstanding that in some States and cities stringent laws, with penalties of heavy fines and imprisonment, have been resorted to to stay the hurtful progress of the habit. Arrests are constantly made in San Francisco under a city ordinance, but, seemingly, without avail, and the vigorous legal prohibition of Nevada effects but little, if any abatement of the evil. The importations of smoking opium into America have steadily increased during the last ten years. The number of Chinese smokers in the country is estimated at 10,544, and, calculating upon the same estimate as in the American cases, they consume 50,240 pounds of this drug in a year. Combined, the consumption reaches the startling figure of 69,240 pounds, making the cost for the total indulgence the enormous sum of over $2,900,000. A quantity of the opium used is also smuggled, and is not included in the above estimate, and some of it also is impure. The injurious effect of this consumption is thus increased greatly, being bad enough when the pure drug alone is employed, as it leaves 33 per cent. of ash, six grains only of which is enough to paralyze a rabbit when hypodermically injected. The last point to be noted is that the repulsive spectre of the emaciated cadaverous creature to be found everywhere among Chinese votaries is seldom, if ever, seen among American opium-smokers. Nor, again, is the smoking of the drug so injurious a manner of introducing it into the system as the method of eating it or injecting it hypodermically. —*Times.*

A SUPPLEMENTARY BLADDER.—Dr. L. R. Dibble, of Albion, Michigan, sends us a case of a man, aged seventy years, who was afflicted with phimosis for twelve years, and whose foreskin became pouched in consequence of difficult micturition. When this pouch was distended it measured nine inches in circumference. The patient would pass his urine into this pouch, and then relieve the distention by a milking process. Circumcision effected, of course, a complete cure.

OPIUM-SMOKING AS A THERAPEUTIC MEASURE.—There is morally and medically as great a difference between him who uses morphia hypodermically, or opium by the mouth, and him who smokes opium, as there is between the man who drinks raw spirits and absinthe "by himself" and him who takes his wine or beer in company.

I am led to believe, from what I saw, that opium-smoking may become an important therapeutic appliance in many cases of distressing thoracic affections, particularly in irritable phthisis and bronchitis. The great objection is, that it may become an inveterate habit.—Cor. *Chicago Med. Review.*

DR. S. H. WEEKS, of Portland, has been appointed by the Maine Medical School to the chair of Surgery, made vacant by the death of Dr. William Warren Green. Dr. Frederick Henry Gerrish, of Portland, was appointed lecturer on Anatomy, and Dr. Charles O. Hunt, of Portland, lecturer on Materia Medica and Therapeutics.

A MUCH-NEEDED REFORM.—The average medicine-chests on board of merchant ships are a disgrace to the vessel, the men who put them up, and to the age we live in. They, for the most part, contain the poorest of drugs, which are sold at exorbitant prices, put up in the slouchiest manner, and are accompanied by a small book of wretchedly prepared medical bosh. The Marine Hospital Service should indicate officially what should be the contents of a ship's medicine-chest, and should prepare a proper work, simple in its language, and shorn of high-sounding phrases unintelligible to the average seaman, to accompany the chest. This work should in part be devoted to simple instructions in surgery, and the medicine-chest should be supplied with some of the lesser surgical instruments.—*Nautical Gazette.*

STORIES OF DR. NÉLATON.—The *XIXe Siècle* relates of Dr. Nélaton that he was accustomed to say: "If you have the misfortune to cut a carotid when performing an operation, remember it takes two minutes for syncope to supervene, and as many more before death occurs. Now, four minutes are four times the time required for a ligature, provided you don't hurry yourself—never hurry yourself."

The *Temps* says: "It is related that, when he began his studies, he worked with such ardor that he often refused himself the time necessary for sleep. He procured a plank some five or six feet long and forty centimetres broad, the extremities of which he placed on two chairs. He lay upon it, holding his book open above him. It is said that in this position the need of sleep is less readily felt. When, despite him, his eyes closed and the book fell, the shock disturbed his balance and he followed the book. The shock aroused him, and he got up and began his work again."

METASTATIC PAROTITIS.—J. Brooke, Assistant Surgeon United States Army, writes: "In connection with the article by Dr. Page on 'Metastatic Parotitis,' in the RECORD of September 10th, the following case may be of interest. It occurred several years ago, and only the prominent points are recollected by me now.

"A man of middle age was kicked in the abdomen by a horse. I saw him a few hours after, and found no external marks of violence, but decided evidences of severe shock, such as cool skin, anxious expression, etc. Reaction occurred, and was followed by

moderate symptoms of inflammation of the peritoneum to a limited extent.

"Soon the *right* parotid gland began to swell, and went on rapidly to suppuration. The pus was evacuated, but the discharge continued to be very profuse for a long time, until the gland appeared to be almost entirely destroyed.

"The facial nerve, where it passes through the gland, was either destroyed in its continuity, or otherwise permanently damaged, for complete paralysis of the muscles of that side of the face soon appeared, and continued after recovery was otherwise complete.

"I saw the man some five years afterward. He was then in good health, but there was not the slightest improvement in the paralysis."

DIPHTHERIA STILL RAVAGING RUSSIA.—The Russian journals publish terrible details of the diphtheria now epidemic in Russia. It is reported that in certain communes and parishes all the children under fifteen years old have died. The origin of the attack dates from 1872, when the disease first appeared in Bessarabia. Since then it has spread far and wide over the south of the empire, whence it lately began to make rapid progress toward the east and northwest. In Pultawa, a province of considerably less than 2,000,000 inhabitants, there have been 45,543 cases, of which 18,765 were fatal.

REMARKABLE WOUNDS OF THE STOMACH.—Dr. A. Dunlap, of Springfield, Ohio, communicates the following interesting and instructive case:

"In 1869 I had a case which exhibited the wonderful tolerance with which the peritoneal cavity bears wounds. I was called to a young man, aged twenty, robust constitution and uninterrupted good health. He had fallen with his stomach on a rapidly revolving shaft, just where it was fastened by a half-inch iron bolt, the bolt projecting about an inch. His clothing caught and held him tightly against it, whilst the revolving bolt cut the wall of the abdomen and the stomach, drawing the latter out of the cavity, and making a wound five inches long in the wall and four and one-half inches in the stomach. It occurred just after he had eaten a hearty meal. I saw him about an hour after the accident. There was no appearance of shock in his pulse, nor of pain in his countenance. The stomach was partly drawn out of the wound, also a very considerable portion of the left lobe of the liver. The former was partially emptied of its contents, but none had entered the abdominal cavity: the food that remained was just as he had eaten it. The bleeding had entirely ceased, and there was trickling from the rent in the organ a perfectly clear fluid. In about another hour I had a physician (and chloroform) to assist me in dressing the wound. After giving him chloroform, I took the stomach up in order to empty it completely, but the chloroform sickened him, and he began to make efforts to vomit. I could feel the vermicular motion of the stomach as I held it, the pyloric orifice approaching toward the cardiac. The muscular contractions gaped the wound, and the pyloric orifice was forced out until it came plainly to view, the stomach being almost completely turned wrong side out. After several efforts at vomiting, the contents of the duodenum began to come in jets. It was of that dark, bilious color which we see in vomiting from an empty stomach. After the vomiting ceased, I cleansed the stomach, and accurately stitched the edges of the wound in that organ to the edges of the peritoneum of the wound in the wall of the abdomen by closely applied interrupted sutures, and then closed the wound. He came from under the chloroform without any appreciable shock. For thirteen days the pulse never rose above ninety, and only a slight increase in temperature. There was no pain or tenderness over the abdomen. The peritoneum united rapidly, and the stitches came away, and left a healthy granulated surface. But the patient was rapidly weakening. The food taken was sufficient to nourish him, and was digested, as I could see it through the large opening remaining in the walls; but it was forced out through this gap by the action of the stomach, and not down into the duodenum.

"He remained bright and cheerful with all these symptoms, till the thirteenth day, when he had a large watery stool. His pulse immediately rose from 90 to 120, and then to 140. In six hours he had another evacuation, and in a few minutes died in collapse. His friends refused a post-mortem examination. The man certainly did not die from inflammatory action, but from rapid exhaustion and the collapse caused by the large watery stool. The extensive surface of the stomach that had become adherent to the walls of the abdomen prevented the vermicular motion from passing the nourishment into the duodenum.

TRI-STATE MEDICAL SOCIETY will hold its seventh annual meeting at St. Louis, October 25th, 26th, 27th, 1881.

THE DIFFICULTY IN FINDING A BALL IN THE DEAD BODY.—Dr. Wooster Beach, of this city, whose extensive experience in autopsical examinations is worthy of great respect, says:

"Some of our wiseacre scribes of the daily press, and, it may be added, a few medical men in the President's case, have insisted that an attempt should have been made to extract the ball at some time during the course of treatment.

"Having had a very considerable experience in autopsies, it has fallen to my lot to trace the course and discover the location of many pistol-balls in the dead body. In some cases this is by no means an easy task. Through certain tissues the mark left by the passage of the ball closes up so as to be almost imperceptible. Coagulated blood in recent cases, and the products of inflammation in old ones, burrow into parts near the track, and so disturb or obliterate it as to make it impossible to judge by its means the course taken by the ball.

Its final location is often quite as difficult to find, and in some cases cannot be discovered except by removal of quite a large part of the body where it is supposed to be, and thoroughly mincing it. I have frequently spent hours in such an endeavor, and in one or two cases have not been able to find the ball at all.

Persons inexperienced in making such *post-mortems* may ascribe my want of success to a lack of skill. On this point I am willing to abide by the judgment of those who have had practice in this kind of work.

If the difficulty of discovering the course and location of a ball may be so great in a dead body, where we may cut, tear, or even entirely remove organs at pleasure, would it not be insanity to attempt the removal of the bullet from a living person, when its exact seat was unknown, or even uncertain?"

MEDICAL FEES.—Dr. Samuel W. Francis' advice is, "Temper the wind to the shorn lamb," but *shear* the lamb!

# Original Communications.

## INJURIES TO THE HEAD,

### Followed by Lesions of the Spinal Cord, Cerebral Symptoms being either Very Slight or Entirely Wanting.

By L. PUTZEL, M.D.,

Neurologist to Randall's Island Hospital.

Case I.* —Jeremiah M——, forty-two years of age, born in Ireland, laborer, married; admitted to Randall's Island Hospital, May 20, 1881. The family history is unimportant.

*Previous history.*—The patient has been a moderate drinker since the age of twenty years; he gives no venereal history, and always enjoyed good health. Ten weeks ago, while loading wood on one of the docks, a stick was thrown out of the vessel, striking him on the top of the head. He was rendered unconscious, and remained so until the next day, having been taken in the meantime to the New York Hospital. When consciousness returned, there was complete paralysis of the limbs, with partial paralysis of the left side of the face; the patient could not articulate distinctly, and the tongue seemed thick and unwieldy; there was complete abolition of sensation below the neck, but the face was normal in this respect; the special senses were not affected. The bladder and bowels were normal. During the first two weeks there was severe headache, but this gradually diminished and then disappeared. At the end of the second week also, motion and sensation began to return in the limbs. The patient got out of bed at the end of three weeks, and was able to walk by holding to the bed-post; within four to five weeks he improved to such an extent that he could walk, though very poorly, without any support; gradual improvement continued until his admission to this hospital.

*Present condition.*—The patient is a large, muscular man, appetite good, sleeps well; mental powers unimpaired. Nothing abnormal was discoverable in the cerebral nerves. There is slight rigidity of the muscles of the legs in walking, most noticeable on the left side, with a perceptible stiffness in the gait; the left leg does not bend at the knee on walking, and the feet are dragged stiffly over the floor; there is loss of power in both hands, the dynamometer being forced to 48 in the right hand and 30 in the left; there is diminished power in both legs, most markedly in the left; there is no appreciable atrophy of the limbs; the electrical reactions are normal to both currents in all the muscles.

Sensation is normal in the right arm; it is diminished in all its varieties over the left arm and leg, and also the right leg. Sensation to touch and heat is abolished over the anterior and outer surface of the right thigh, and the right gluteal and iliac regions; sensation to pain and cold are merely diminished in these regions.

The cutaneous and patellar tendon reflexes are increased in both legs, but much more markedly in the left. Ankle clonus is present on the left side, but not on the right.

Physical examination of the viscera furnishes entirely negative results.

September 17th.—The spastic gait is more marked than upon admission (greater stiffness of the legs on walking, and the soles of the feet dragged and scraped more markedly along the floor). In addition, beginning contracture is found in the flexor muscles of the forearms, especially on the left side; increased tendon reflex of the flexor and extensor muscles of the forearms; there is a feeling of coldness over the anterior and outer surfaces of the right thigh and right gluteal and iliac regions, and both feet and ankles. In other respects the condition of the patient is unchanged.

Case II.—Thomas R——, aged fifty-five years, sailor, admitted to the hospital, July 14, 1880. The family history is unimportant.

*Previous history.*—The patient has been a hard drinker for the past ten years; had gonorrhœa several times, but no other venereal disease; he was never sick (save from drunkenness) until the accident which led to his present condition. Two years ago he fell from a ship's foremast-head to the deck, striking on the right side of the forehead and the right shoulder. He was picked up unconscious and taken to St. Vincent's Hospital; does not know how long the unconsciousness lasted. Upon recovering his senses, there was general and complete paralysis below the neck. There was no facial paralysis, but, for the first two weeks, speech was so much affected that he could not speak distinctly, although he could talk aloud; the front teeth of the upper jaw were knocked out, and those of the lower jaw loosened. He states that sight, audition, gustation, and olfaction were not affected; the action of the bladder and bowels remained normal. He was in the hospital a month, improving very little during this time. After returning home, he began to improve, and in three months was able to walk a little, the legs improving much more rapidly than the arms. He continued to improve for five or six months, when he began drinking again, and at once grew worse, the paralyzed limbs, especially the legs, becoming weaker and stiffer. The patient continued growing worse for three months, at the end of which time he could scarcely stand. He was admitted to Randall's Island Hospital on July 14, 1880. During the first three months after his admission he suffered from diarrhœa, but there has been a tendency to constipation since that time; the power of micturition has always been normal. He was able from the first to feel distinctly, though not in an entirely normal manner, in the paralyzed parts. Of late he has noticed that the hands and fingers cannot be readily extended, and that the foot is flexed with greater difficulty; he has spasms in the muscles of the legs at night. The patient spat blood for some time after the fall, and also four months ago; he has had a cough for some time and lost thirty-five pounds in weight; never had night-sweats.

*Present condition* (July 14, 1881).—The patient is lean and somewhat emaciated; appetite moderate; no night-sweats, but an annoying cough; sleep disturbed on account of cramps in the legs; bladder normal; bowels very constipated. Nothing abnormal is discoverable in the cerebral nerves.

Physical examination of the lungs furnishes the following signs at the apices: increased vocal fremitus, dulness, increased vocal resonance and bronchial whisper; the expiratory sound is raised in pitch, prolonged, and is tubular in character; mucous râles are heard after coughing. These signs

* For the records of the following cases I am indebted to the kindness of my house physician, Dr. T. S. Axtelle.

are most marked on the left side. The other viscera present nothing abnormal.

Upon directing the patient to walk, his body is found to be bent forward, the legs being slightly flexed at the knees and quite stiff. The limbs maintain this stiffened position during locomotion, the soles of the feet being dragged along the floor and never raised. There is also a less degree of stiffness at the hip-joints. Upon attempting to stand on the toes, clonic contractions are excited in the muscles of the calves, rendering the performance of the act impossible. The patient states that this spastic condition of the muscles has existed for the past two or three months, and is gradually progressing. There is diminished muscular power in both legs, but most markedly in the left; both feet can be extended on the legs, but the power of flexion is weakened, especially in the left foot; the left leg is more rigid than the right. Pain is felt in the knees on rising, and in the lumbar region; there is also a constant, dull pain along the course of the sciatic nerves and their branches; the legs always feel cold.

The hands and fingers maintain a position midway between flexion and extension, giving them somewhat of the bird's claw appearance. The arms and forearms are freely movable. There is a spastic condition of the flexors and extensors, especially of the former; flexion and extension of fingers are interfered with, the latter most markedly. The index fingers fly back like a spring, after they have been flexed or extended. The patient can pick up a pin clumsily and write indifferently. There is very little more than the normal difference in the measurements of the limbs on the two sides of the body, though there is more loss of power on the left side than the right.

Tactile sensation is slightly diminished throughout the body below the lumbar region, and about equally on the two sides; it is markedly diminished in the forearms and hands, especially over the posterior surface of the forearms, the dorsal surface of the hands and the tips of the fingers. Sensation to pain is also diminished over these regions; it is increased in both legs, most markedly in the left. Sensation to heat and cold is diminished over both lower extremities, especially on the right; it is also diminished over the forearms and hands, about equally on both sides, but chiefly on the posterior aspect.

The cutaneous reflexes are markedly increased in the lower limbs. Patellar tendon reflex and ankle clonus are exaggerated in both limbs, chiefly in the left. Hamstring clonus is present on the left side, but not on the right; adductor and cremaster reflexes are present on both sides; there is increased tendon reflex of all the flexors and extensors of the forearms.

September 14, 1881.—Very slight changes are noticeable from the date of last report. The cutaneous and tendon reflexes throughout the body are somewhat increased. There is greater diminution of tactile sensation and of sensation to pain over the posterior surface of the forearms and the dorsal surface of the hands and feet; hyperæsthesia of palms of hands and soles of feet, and also, to a less degree, of the inner surface of the legs. Otherwise the sensations remain as before.

There is increased contracture of the flexor and extensor muscles of the forearms and of the calves of the legs, causing the characteristic "spastic gait" to become more marked. In other respects the condition of the patient was unchanged, and he soon left the hospital.

These cases are interesting on account of their rarity, and very few analogous ones can be found in medical literature. An analysis of the symptoms serves to show that, although the injury was sustained by the head, the cerebral symptoms were of a mild and temporary character in the first case, and almost entirely absent in the second, and could be satisfactorily explained either by simple cerebral concussion, or the formation of a few minute hemorrhages in the brain, the effects of which soon disappeared. In fact, the entire group of symptoms may be satisfactorily accounted for on the view that a hemorrhage occurred at the time of the accident in the cervical portion of the spinal cord, this lesion being followed by myelitis in the neighborhood of the clot and by descending degeneration in the lateral columns of the cord.

Duret has shown by physiological experiments that blows upon the forehead and vertex are apt to be followed by hemorrhages in the medulla oblongata, and sometimes in the spinal cord. Westphal, in his experiments on the production of epilepsy in animals, has also shown that blows upon the vertex give rise to hemorrhages in the medulla oblongata and upper portion of the spinal cord. Why the brain, in the cases under consideration, apparently escaped with such slight injury, we are unable to state, but in another case under my observation (the notes of which I have unfortunately lost) the cerebral symptoms were even less marked. The patient in question, a man about forty-five years of age, while diving in the water, struck his forehead against a log and was dragged out in an unconscious condition. The unconsciousness lasted for two or three hours, and when the patient recovered his senses, he found himself paralyzed in all the limbs, no cerebral symptoms whatever being present. Within a couple of days afterward the paralysis of the lower limbs had entirely disappeared, the sole remaining symptom being a cervical paraplegia. Shortly afterward the patient came under my observation, and I discovered a moderate degree of paralysis of the upper limbs, with slight and uniform atrophy of the affected muscles, and slight diminution of faradic muscular excitability; in addition there was a feeling of numbness in the hands, but no appreciable anæsthesia; he also had some tenderness over the middle of the cervical spine. In other respects the patient's condition was entirely normal, and he made a complete recovery within a couple of months under the use of counter-irritation to the cervical spine, faradism to the paralyzed muscles, and ergot and iodide of potassium internally.

In this case, also, there can be no doubt that the injury to the cranium had been followed by a hemorrhage into the cervical cord, although the brain had apparently escaped without injury.

---

Fecundity of Elephants in Confinement.—Barnum's baby elephant, born at Philadelphia, is growing rapidly, and is a vigorous creature in its third year. Its mother is again about seven months along in pregnancy, and it is therefore not unlikely that a second one will be born in this country. The sexes in Barnum's herd of elephants pair readily in confinement. We learn on good authority that an American resident in India of thirty years, never heard of an elephant being born there, and was astonished at learning of the birth of one in the United States.—*Am. Naturalist.*

## JARVIS' OPERATION IN HYPERTROPHIC NASAL CATARRH.

### With Report of Three Cases.

By CARL SEILER, M.D.,

LECTURER ON LARYNGOLOGY AT THE UNIVERSITY OF PENNSYLVANIA.

It is not my intention to write a dissertation on nasal catarrh in its various phases, nor to consider the different methods of treatment recommended for the cure of this malady, but simply to give an account of my experience in operating with Jarvis' wire snare écraseur upon a number of cases, and to point out a few of the minor, but, to my mind, essential details of manipulation which insure success in the operation.

Case I.—S. R——, aged twenty-six, clerk, presented himself at my office, complaining of cough, shortness of breath, frontal headache, watering of the eyes when in the open air, continual clearing of the throat, and copious expectoration of thick, glairy mucus. He spoke with a thick, nasal voice, stating that his nose had been stopped up for two years, and that he was obliged to moisten his throat several times during each night. He had a good family history, and an examination of the chest revealed no signs of lung disease. The laryngoscopic mirror showed congestion of the laryngeal mucous membrane, as well as of the pharynx, which was granular. On introducing the nasal speculum into the anterior nares, I found the left nostril clear, but the right one was partially obstructed by an anterior hypertrophy, springing from the lower turbinated bone. A rhinoscopic view was easily obtained, on account of the sluggishness of the soft palate, amounting almost to a paresis. In the mirror I saw two large growths, of a purplish color, entirely filling up the posterior orifices of the nostrils and thus giving rise to the stenosis. The mucous membrane of the posterior nares was in a state of chronic inflammation, and covered with thick whitish mucus. The adenoid tissue of the vault of the pharynx—the so-called pharyngeal tonsil—was also somewhat enlarged.

I at once introduced Jarvis' écraseur through the left nostril, and, by directing the motions of the loop of the instrument, as seen in the rhinoscopic mirror (Fig. 1), held in the left hand, succeeded at the first trial in engaging the growth and slipping the wire over its pedicle. I then gradually tightened the screw at short intervals, always stopping when the patient winced. In the course of three-quarters of an hour, I found that I had come to the end of the screw-thread of the instrument, and yet the growth had not been cut through by the wire. This was caused by my having made the loop too large before snaring the growth, and I was obliged to untwist the ends of the wire and shorten it before it was possible to proceed with the operation.

Having thus shortened the loop, I again gave a turn to the milled nut every few minutes, until, having consumed more than two hours, patience ceased to be a virtue, and at the risk of hemorrhage, I withdrew the instrument, dragging with it the growth, which was then about the size of a small cherry. On examining the instrument, I found that the growth had long been severed from its connection with the nasal mucous membrane, and the loop had been drawn into the canula of the instrument fully half an inch, dragging with it a shred of tissue. This explained the fact that I had not felt a diminution in the tension of the wire as soon as the growth had been cut loose.

There was no pain felt by the patient during the operation, except a peculiar feeling in the ear, and but a few drops of blood escaped. The nostril was cleared of obstructions, thus enabling the patient to breathe through it freely for the first time in two years. The relief he felt was clearly seen in the expression of his face, and he left the office, as he declared, "a different man."

On the following day he came again, stating that there had been no bleeding from the nose, that he had slept throughout the whole night without once awaking, and that he was almost entirely free from the oppression in the chest which had troubled him before the operation. On examination I could not find the wound at the site of the growth, but noticed a puckering of the mucous membrane at that place (Fig. 1). The patient insisted upon having the other nostril cleared of obstruction, which I proceeded to do, taking care, however, to measure the loop before introducing the instrument into the posterior nares. I succeeded in removing the growth, which was somewhat smaller than the first one, in a much shorter time, and also without any pain or hemorrhage.

After a rest of a few days I began to treat the chronic inflammation of the nasal mucus membrane by means of mild astringent sprays thrown into the nasal cavities through the nostrils, and removed an anterior hypertrophy with the galvano-cautery knife. In the course of a few weeks the patient was to all intents and purposes cured of his trouble.

Case II.—Miss M. T——, aged twenty-four years, school-teacher, applied to me for relief from an obstruction in the nose, which became worse at night when in the recumbent position. On questioning her I learned that she had been troubled with the usual symptoms of nasal catarrh for several years past, and that of late her throat had become painful, and her voice was frequently hoarse; she had a cough with thick, yellowish white expectoration; oppression in the chest; falling off in weight, and an almost continuous frontal headache. She attributed her trouble to the constant inhalation of chalk-dust from the black-board in the school-room. Her family history, in regard to lung disease, was not quite good, her grandfather on her mother's side having died of phthisis.

An examination of the chest showed slight prolongation of the expiratory sound, but no other signs of lung trouble. The larynx was seen to be in a state of chronic inflammation, with a slight abrasion on the outer arytenoid fold. The pharynx was dry, and studded with enlarged follicles. A rhinoscopic examination was very difficult to make, on account of an inability on the part of the patient to keep the velum relaxed. I obtained, however, a sufficiently extended view of the posterior nares to see some whitish growths, partly filling up the posterior orifices of the nares, and hanging from the middle turbinated bones by a short pedicle. The anterior nares were clear of obstructions in the shape of hypertrophied mucous membrane. Having prepared the snare, taking care to determine the size of the loop, I introduced the instrument into the nostril, and the rhinoscopic mirror into the fauces, but was unable to obtain a view of the wire loop in the post-nasal cavity. I therefore trusted to my knowledge of the position of the growth, and endeavored to engage it in the snare. After many fruitless efforts to catch it, I had to desist, on account of faintness

overcoming the patient, due probably to the irritation of the mucous membrane produced by the frequent introduction of the instrument.

The next day she returned, and, before again attempting to catch the growth with the snare, I introduced a Eustachian catheter into the nares, through which was passed a piece of *violin* string until its end appeared below the margin of the soft palate, where it was seized with a pair of forceps and drawn out through the mouth. The catheter was then withdrawn, the other end of the string projecting several inches from the nostril, and both ends were secured by passing them over the patient's ear, having previously drawn the velum away from the wall of the pharynx, without making undue traction. The presence of the catgut being well borne, I was enabled to obtain a good view of the posterior nares, and engage the hypertrophy at the first introduction of the snare. (Since then I have obtained, through the kindness of my friend Dr. W. C. Jarvis, his combined tongue-depressor and rhinoscopic mirror, and his tape-holders, shown in Fig. 1,* described by him in

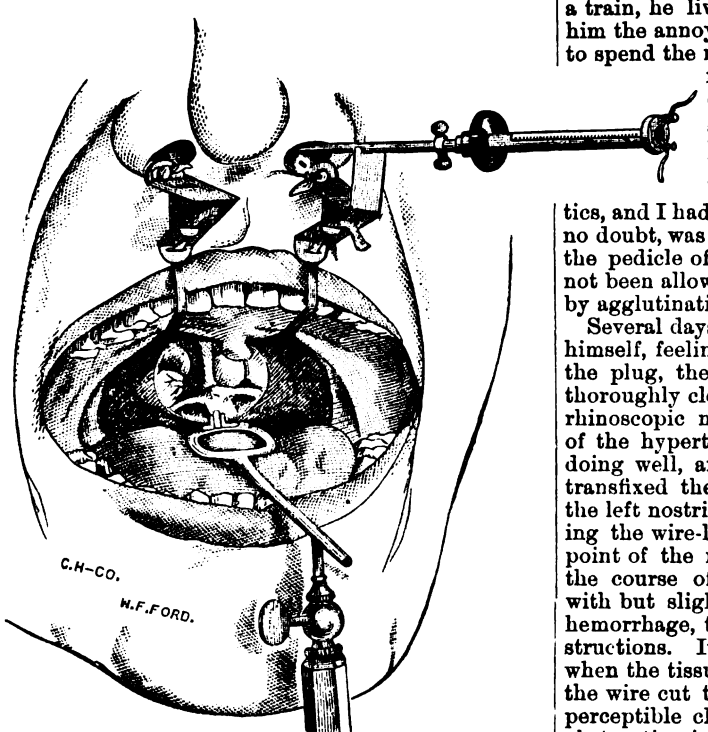

Fig 1.

a paper read before the American Laryngological Association, session 1880,† and I find that the procedure of securing the soft palate, and the practice of watching and directing the movements of the snare in the posterior nares, are greatly facilitated.)

Both hypertrophies were removed on successive days, each operation occupying about an hour. There was no pain or hemorrhage, and the patient, under appropriate after-treatment, rapidly regained her former good health.

Case III.—Mr. S. O——, aged thirty-two years, merchant, consulted me in regard to nasal trouble, consisting in stoppage of the nose, constant hawking and expectoration of thick, stringy mucus, loss of sense of smell, and all the other well-known symptoms of hypertrophic catarrh. Perhaps the most prominent symptom was the complete absence of nasal resonance in his voice. On examination, I found the anterior nares almost completely obstructed by anterior hypertrophies, springing from the lower turbinated bones and touching the septum. A rhinoscopic examination showed a large posterior hypertrophy projecting from the upper turbinated bone, on the right side, into the post-nasal cavity. I decided to remove the posterior hypertrophy first, but on introducing the snare I had some difficulty in engaging the growth, on account of the great irritability of the nasal mucous membrane, causing the patient to sneeze at the slightest touch. Finally, however, I succeeded, and began to tighten with the milled nut, when the patient informed me that he would have to leave my office within three-quarters of an hour, in order to make a train, he living out of town. Desirous of saving him the annoyance of missing the train and having to spend the night in town, I hurried the operation rather more rapidly than I would have otherwise done. In consequence, the growth was severed from its connection within thirty minutes, but a copious hemorrhage followed, which could not be stopped by the application of styptics, and I had to plug the nares. This hemorrhage, no doubt, was due to the fact that in cutting through the pedicle of the hypertrophy sufficient time had not been allowed for the vessels to become occluded by agglutination of their walls.

Several days afterward the patient again presented himself, feeling greatly relieved. He had removed the plug, the hemorrhage having stopped. After thoroughly cleansing the nasal cavities, I saw in the rhinoscopic mirror a small raw surface at the seat of the hypertrophy, which seemed, however, to be doing well, and I therefore left it alone. I next transfixed the base of the anterior hypertrophy in the left nostril with a curved needle, and after passing the wire-loop of the snare under the heel and point of the needle, I made rapid traction, and in the course of twenty minutes removed the mass, with but slight pain to the patient, and very little hemorrhage, thus freeing the nostril from all obstructions. It was noticeable that at the moment when the tissue had been compressed to its utmost, the wire cut through it quickly, producing quite a perceptible clink. The other side was freed from obstruction in the same way after the lapse of a few days, and in a very short time all the symptoms complained of had disappeared.

There are in my note-book the histories of a number of other cases of both anterior and posterior hypertrophy, which I successfully operated upon, but as they are more or less like the foregoing ones whose history has been given in detail, I shall not weary the reader with an account of them, but will at once state the conclusions which I have arrived at in treating these cases, both as regards the nature of the hypertrophies, as well as the operation for their removal.

All the cases examined by me invariably presented a constriction at their base, resembling a short pedicle, thus forming a groove into which the wire loop of the snare readily slips and is retained. The surface of this form of hypertrophy is more or less

* Photographed and engraved from a sketch kindly furnished by Dr. Wm. H. Arthur, U.S.A.

† Reprints of this excellent paper may be obtained by applying to Dr. W. C. Jarvis, 128, East Twenty-fifth street, New York City.

corrugated, resembling that of a hobnail liver, and their color is either a yellowish white or a purplish red, the former being tougher and of a more fibrous nature than the latter, which are more liable to bleed on slight provocation.

Thin sections of these hypertrophies (Fig. 2), when examined under the microscope, show the epithelial layer of the mucous membrane to be intact, and the mucous membrane proper normal; the sub-mucous tissue, however, is charged with a small-celled infiltration of inflammatory origin; the

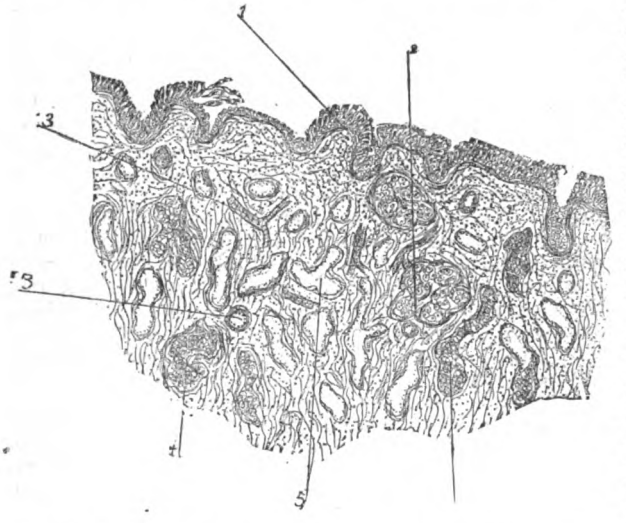

FIG. 2.—Section of Posterior Hypertrophy, × 250: 1, mucous membrane; 2, glands; 3, arterioles; 4, venous sinuses, filled with blood-corpuscles; 5, venous sinus empty, showing lining of endothelium.

mucous glands and follicles are hypertrophied and filled with proliferated epithelium. The substance of the tumor is made up of fibrous tissue, containing blood-vessels in the shape of small arteries and arterioles, and numerous large venous sinuses lined with endothelium, which shows a tendency to proliferate. This tissue is identical in appearance with that found in the corpora cavernosa of the penis and in angiomata or erectile tumors. Those hypertrophies which show a yellowish white color in the rhinoscopic mirror have their fibrous tissue more dense, and the venous sinuses are not as numerous as in those which appear dark-red or purplish. This fact explains the difference in density noticed whilst snaring them off.

The presence of these hypertrophies, whether in the anterior or posterior nares, decreases materially the volume of the nasal cavity, and thus interferes with the free communication between the air contained in this cavity and the outer air, hence the nasal resonance of the voice is changed. This change is noticeable, not only in the singing voice, and *all* its registers, but also in the speaking voice, as I have pointed out in a paper read before the American Laryngological Association, session 1881.

The success of Jarvis' operation, *i.e.*, the successful removal of the hypertrophies without undue pain and hemorrhage and without loss of time, depends mainly upon the observance of details on the part of the operator—details which suggested themselves to me in the first cases I operated upon, and especially in those whose history I have already briefly related.

The snare which I use is one that has been materially improved by Dr. Jarvis since he described it in his first paper,* by adding a scale on the screw thread, to measure the size of the wire loop; by substituting a cross-bar for the milled button intended for a finger-rest, and by adding a device for fastening the ends of the wire more easily and quickly than with the old instrument.† The measuring of the wire loop is of great importance, in order to prevent the mishap which occurred to me in Case I., and my method of procedure is as follows:

After the ends of the wire have been made fast, a piece of hard wood, shaped like a wedge, is thrust into the loop. The triangular base of the wedge is rounded off and its narrowest part rests upon the end of the main tube, whilst the wire is drawn tightly over it by pulling upon the slide tube. The circumference of the wedge is first measured by making a wire loop of the same size and drawing it just within the orifice of the main tube, at the same time noting the distance traversed by the slide tube. This distance is added to that previously registered by the slide tube when it clasped the wooden wedge, and the number found will be that indicating complete section of the hypertrophied tissue.

The loop might be measured by drawing it into the instrument, but then the wire becomes "kinked" and is very apt to break at that point during the operation, while when measured in the manner described the loop retains its shape. Before introducing the instrument into the anterior nares, when posterior hypertrophies are to be removed, the loop should be made as small as possible without distorting it, by pulling down the sliding tube. As soon as the end of the instrument has entered the post-nasal cavity, the loop is again enlarged by pushing up the tubes to which the ends of the wire are fastened. This has the effect of throwing the loop out and bending it toward the growth to be removed, thus greatly facilitating the catching of the hypertrophied tissue. The cross-bar on the instrument indicates the position of the tube in relation to the natural bend of the loop. Under no circumstances should an attempt be made to engage the hypertrophy without directing and watching the motions of the loop in the rhinoscopic mirror. It is true that there is no projection in the nares which could engage the snare that is not pathological and therefore should not be removed, as Dr. Bosworth has pointed out;‡ yet I do not think we are justified in subjecting our patients to the pain and inconvenience, not to mention the loss of time occasioned by our efforts in groping for the growth in the dark, when by using Jarvis' combined tongue-depressor and rhinoscope in connection with the tape-holders for retracting the soft palate, a sure means is provided for seeing what we are doing.

The variance of Dr. Bosworth's experience from mine in the use of the tongue-depressor and rhinoscope was evidently due to the incompleteness of the instrument at the time of his writing.

As soon as the wire has slipped into the constriction at the base of the hypertrophy, the loop should be carefully tightened around this tissue by pulling down the slide tube. When the traction upon the wire becomes perceptible the milled nut is run

* Loc. cit.
† MEDICAL RECORD, April 30, 1881.
‡ Jarvis' Operation: Its Relation to Nasal Catarrh: MEDICAL RECORD, July 9, 1881.

down, further traction being made by rotating it. By giving a turn to the milled head until the patient winces, every minute at first, and later every three or four minutes, the growth can be snared off in the course of an hour or so. As soon as the point marked on the scale has been passed by the end of the sliding tube, a number of turns should be given to the milled nut to insure complete section of that portion of the mucous membrane overlying the end of the tube, and then the instrument can be withdrawn. The growth usually comes out clinging to the écraseur by a shred of tissue which has been drawn into it by the wire, but sometimes, although severed from its connection, it remains in the nasal cavity and should then be removed at once with a pair of forceps. After the operation the patient should be cautioned against blowing his nose, for fear of opening the agglutinated venous sinuses by the mechanical vibration, and so starting a hemorrhage. If any bleeding should follow the operation, it can usually be stopped by throwing the spray of a solution of perchloride of iron into the nostril.

In removing anterior hypertrophies by means of the snare, a much finer wire should be used than is employed in operating upon the posterior forms of hypertrophy, and as the blood-supply to that portion of the mucous membrane of the nose is much more limited, they can be cut off quickly. These sessile growths can readily be engaged in the loop by first transfixing their base with a slightly curved needle until its point projects above the growth into the nasal cavity.* The loop is then introduced in such a manner that the portion of the needle projecting from the nostril is above the end of the instrument, while the end of the wire loop is under the needle's point, very much after the manner of a hare-lip suture. The wire is thus prevented from slipping off and the hypertrophy is readily secured and is removed sticking to the needle.

I may here state that in making use of the expressions "anterior" and "posterior hypertrophy" in this article, I have taken it for granted that the reader is acquainted with the divisions and their modifications, as first pointed out and described by my friend Dr. Jarvis, and now generally accepted by the laryngological profession in this country.

The great and immediate relief following Jarvis' operation in hypertrophic catarrh and the minimum amount of pain and hemorrhage attending the removal of nasal hypertrophies, places in the hands of the physician a means of quickly and safely curing one of the most annoying and widespread maladies which human flesh is heir to, and I take this opportunity to express my personal gratitude to Dr. Jarvis, and my admiration of his ingenuity in presenting to the medical profession so admirable an instrument as his snare.

**The Six Healthiest Cities** in the United States, as measured by the most recent authentic reports, were in the order named: Utica, Dayton, New Haven, Portland, San Francisco, and Lawrence. The six unhealthiest were Charleston, Memphis, Cleveland, Chicago, Hudson County, N. J., and Lynn. The six unhealthiest in the world were St. Petersburg, Charleston, Malaga, Alexandria, Warsaw, and Buda-Pesth.

* The Radical Cure of Nasal Catarrh, by William C. Jarvis, M.D.: Transactions of American Medical Association for 1881.

## ON STRICTURE IN THE UPPER PORTION OF THE RECTUM AND IN THE SIGMOID FLEXURE.

By CHARLES B. KELSEY, M.D.,

Surgeon to St. Paul's Infirmary for Diseases of the Rectum, New York.

A stricture of the upper portion of the rectum, or of the sigmoid flexure, differs in so many essential particulars of pathology, diagnosis, and treatment from the same conditions as usually found in the lower three or four inches of the bowel, as to require to be studied from a special standpoint. The confidence in diagnosis and the facility in treatment, which come from the sense of actual contact with the finger in the one case are entirely lost in the other, and the most skilful diagnostician may at any time find himself afloat in a sea of uncertainty as to the actual condition and the proper method to be pursued in its treatment.

The disease we are now considering is one of middle or advanced life, and a stricture of this part of the bowel, which is due to disease in the intestinal wall itself, and not to pressure from without (the latter class of cases we shall leave out of consideration), is, in the vast majority of cases, of cancerous origin. The same statement has often been made concerning strictures of the lower portion of the rectum, but without the same foundation in fact, as any one with much experience in such cases will soon have impressed upon him. It is a very unsafe rule to consider the majority of strictures of the lower end of the rectum as necessarily malignant; but the many varieties of non-malignant disease to which this part of the rectum and the anus are subject, and which result in ulceration, contraction, and finally in stricture, are not to be found higher up. Practically there are only two causes of stricture in the upper part of the rectum, cancer and dysentery, though typhoid ulceration and traumatism may in rare cases result in cicatricial contraction. Dysentery may, as a rule, be easily eliminated by a careful attention to the previous history, and therefore the practice of dealing with all of these cases as though in the presence of malignant disease, will seldom lead to error.

The varieties of cancerous growth are the same here as elsewhere in the canal, and chiefly varieties of epithelioma, though scirrhus, encephaloid, and colloid have been met with, and cases of melanoma and true osteoma are on record. The disease tends to encircle the bowel rather than to extend longitudinally, and may produce fatal obstruction, while still limited to a small area, and before causing any secondary deposits, either visceral or lymphatic.

The bowel above the stricture will generally show secondary changes in cases of sufficiently long standing, due to the mechanical effects of the obstruction; and these secondary changes may extend for a long distance, and are particularly to be found in the caput coli. There will generally be found dilatation and corresponding thinning of the wall, though sometimes both dilatation and hypertrophy will be seen. The wall may be as thin as paper, and softened in addition, and at these softened places perforation takes place. The mucous membrane is injected, and in some places eroded. In a case reported by Goodhart,* these changes had gone on to actual gangrene, extending in spots along the trans-

* Med. Times and Gazette, February 28, 1880.

verse and descending colon, and ending abruptly at the stricture, and were undoubtedly due to the intensity of the inflammatory action caused by the retained irritant matters. The bowel is generally distended with gas and fæces, but the latter are more often fluid than solid, though fecal tumors, with their well known characteristics, will sometimes be met.

The symptoms of stricture of the upper part of the rectum are not the same as when the disease is lower down, for the nerve-supply is not the same, nor is the sphincter muscle involved. For this reason the patient is much more apt to suppose himself suffering from chronic constipation and dyspepsia than from hemorrhoids. Pain in the abdomen, not always localized at the left side, pain in the loins and down the legs, obstinate constipation and occasional diarrhœa, are the things usually complained of, and in these there is nothing upon which to base a positive prognosis. The fæces may never present the peculiar ribbon-shape which was so long taught to be characteristic of stricture, for the reason that the passages are often fluid in character, and when solid are accumulated in masses in the rectal pouch below the obstruction, and passed in the natural shape. They are very apt to be lumpy and unformed rather than misformed, but they may be streaked with blood, which is always a valuable sign, and should lead to a careful physical exploration.

The chief symptom of a stricture of the intestine in this or any other part is obstruction. But this may come on gradually, and with the usual signs of intestinal disturbance, or suddenly, in a person to all appearance in perfect health. But whether the obstruction come on suddenly or gradually, the diagnosis is not generally made until it comes. Then we have an almost typical picture of pain over the afflicted part, tympanitis to a marked degree, sometimes a fecal tumor, obstinate vomiting, sometimes of fæces, constant desire to stool, with no relief, and the passage only of watery fluid mixed with blood or mucus, and the serpent-like coils of writhing intestine. With these symptoms there will be a marked change in the general appearance of the patient; the urine will be altered in quantity and quality; there may or may not be febrile reaction, and the patient will die either of exhaustion or in sudden collapse from perforation of the already weakened and over-distended bowel, unless relieved by treatment.

In cases where the condition is more complicated and where secondary deposits—in the liver, for example—have begun to do their fatal work before actual obstruction has begun, these symptoms may all be obscured by the presence of others which shall more readily attract the eye. In a case which I now have under treatment, I had made the diagnosis of cancer of the liver with ascites and great intestinal disturbance some time before my attention was called to the rectum, and it became evident by examination that the affection of the liver was secondary to malignant disease high up in the rectum, which was also gradually involving the pelvic viscera.

A stricture in the location under consideration may be diagnosticated in two ways—by the symptoms to which it gives rise and which we have already enumerated, and by physical examination, but the examination must be conducted with great care and gentleness, and may even then be negative in its results. The attempt to decide upon a stricture in this situation by the use of bougies is altogether unsatisfactory and by no means free from danger. It is unsatisfactory because an obstruction will generally be encountered in trying to pass an instrument of any considerable size through this part of the bowel, and the passage of an instrument of small size, which is much easier, proves nothing. It is dangerous because, with the ordinary rubber rectal bougies, a diseased bowel may easily be ruptured with what may seem to the operator to be no more force than is justified in attempting to overcome the natural obstructions to this part of the passage. The bulbous-pointed bougie on the flexible stem appears *à priori* to be the most suitable for the exploration, but it has two objectionable features. It is not at all an easy instrument to pass, and if passed through an obstruction too much force is required for its withdrawal after the abrupt shoulder is in contact with the stricture. After considerable experiment, I have had a bougie made for myself by Stohlman, Pfarre & Co., of New York, which I like much better. It is very similar to those known as Wale's dilators, but much more flexible than anything in the market, and therefore much safer.

Fortunately, we are not limited to the passage of the bougie for the diagnosis, for if the cancerous mass is of any size, it may be felt through the wall of the abdomen by careful palpation; and if not, and the symptoms warrant it, the sphincter may be stretched or incised sufficiently to allow of introducing the hand into the rectal pouch. Passing the whole hand into the rectal pouch, and then the finger into the sigmoid flexure as far as possible, is a very different affair from trying to pass the whole hand into the flexure, and is free from danger, because the distention by the hand is not carried to the point where danger is located at the reflexion of the peritoneum. Though seemingly a much more serious matter, it is really safer than any forcible use of the bougies, and by it the diagnosis may be rendered certain for all that part of the bowel at present under consideration.

It will at once be seen that the treatment of a stricture here must be conducted on entirely different principles from that of a stricture within reach of the finger. In the latter case we may deal with the disease itself by dilatation, excision, or rectotomy. In the former, one of these measures (rectotomy) is entirely inapplicable, dilatation is of no value and very dangerous, and excision has not as yet been sufficiently tested to be fairly judged. So that, instead of dealing with the disease itself, we are limited to attempts to ward off its natural effects—in other words, to preventing the occurrence of intestinal obstruction, and forming an artificial outlet for the contents of the bowel when obstruction is threatened.

In stricture here, as elsewhere, much may be done by medicinal means in preventing threatened obstruction. The food should be such as leaves the least possible residue, and such residue as there is should be rendered soft and partially fluid by the administration of suitable drugs. In the way of laxatives, a mineral water, or one of the various salts, taken before breakfast, will generally be found sufficient. Purgatives for very obvious reasons are contraindicated. The diarrhœa, which is due to the morbid condition of the bowel above the stricture, may be controlled to some extent by the use of bismuth and morphia, and the general health may be kept up by tonics, among which the compound tincture of cinchona is, perhaps, as good as any.

When obstruction actually exists, much may be done in the way of general treatment before resorting to operation. Food should be almost absolutely suspended; opium should be given in large doses, to allay the peristaltic action of the intestine, and large poultices covering the abdomen will be found to give great relief to the suffering. Dr. Norman Kerr has derived great benefit from the administration of the extract of belladonna in doses of one or two grains at short intervals, in this condition, but the *rationale* of its operation is not understood. No purgatives should be administered, and the bowel should not be tapped with the aspirator, for the reason that it is generally filled with fæces, which for the most part still retain their fluidity, and that in the overdistended condition of the intestinal wall there is no closure of the aspirator-wound by nature, and leakage after withdrawal of the needle is more than likely to occur. When used, a little gas and fluid fæces will alone be removed, and very little relief will be obtained.

The surgical means at our disposal for the relief of this affection are chiefly two: one consists in removal of the cancerous growth through the abdominal wall, and at the same time forming an artificial anus in the left inguinal region at the site of the incision. The other, in opening the bowel above the disease, but making no attempt to deal with the disease itself. The former of these operations is an outgrowth of the great advance in abdominal surgery which has taken place in the past few years. It has been performed four times, and twice with success. The successful cases are those by Gussenbauer,* performed in 1879, and by Czerny, of Heidelberg.† In the former there was no return of the disease nearly two years after the operation, and in the latter there was an interval of six months before the return, which may be considered a satisfactory result. The fatal cases are, one previously performed by Gussenbauer, in which the man died in fifteen hours, of "acute sepsis," and a recent one by Billroth,‡ in a man aged twenty-eight, which proved fatal in thirty-six hours, from incipient profuse peritonitis. The operation consists essentially in opening the abdomen by the incision customary in ligature of the left iliac artery, excising the cancerous mass, stitching the end of the upper segment of the colon to the wound, so as to form an artificial anus, and allowing the lower portion to drop into the pelvis. It is applicable to cases where the disease has not extended beyond the wall of the bowel into adjacent parts, and all that can be said of it at present is that it promises well, and the future may prove it to be one of the great advances in surgery for which the present century promises to be famous.

We shall make no further mention of the various attempts to extirpate extensive disease of this part of the bowel through the perineum, than to say that we believe them all to be unjustifiable.

The only other means of relief is in colotomy, either inguinal or lumbar. The left inguinal operation is, perhaps, preferable, though in the present state of opinion and statistics the surgeon is at liberty to choose between the inguinal and lumbar incision according to his own ideas of facility of operation and subsequent convenience of location, for there is little to choose between the relative dangers of each.

It will often be difficult for the surgeon to decide for or against operative interference in these cases. Two factors enter into the question: 1st, whether or not the patient is likely to survive the operation itself; and, 2d, if this is decided in the affirmative, whether sufficient is to be gained to pay for the risk. The general condition of the patient, the extent of disease as regards secondary deposits, and the amount of pain due to defecation, all have to be taken into consideration. The operation may be indicated to relieve this pain when there is not much chance of actually prolonging life, and it may be indicated to prevent or overcome obstruction where there is no great amount of pain. I am inclined, for myself, to limit the operation to those cases where the pain of defecation is great, and where the disease is still circumscribed, and should not for the choice between death from obstruction and death a few weeks later from exhaustion always have recourse to this extreme measure, but should rather trust to securing a comparatively easy passing away of the patient under the influence of opium. Indeed, many patients will decide the question in this way for themselves when the question in all its bearings is explained to them.

It is a curious fact, that by relieving the over-distention of the bowels by colotomy, the obstruction also will sometimes cease, and passages will again pursue their natural course. Such a case is reported by Goodhart,* where three successive operations for opening the colon above the stricture were resorted to to relieve obstruction, and after each one the passages were again restored to the natural outlet.

## EPILEPSY FOLLOWED BY APOPLEXY.

By CHARLES ANDERSON, M.D.,
ACTING ASSISTANT SURGEON U. S. ARMY.

Although the occurrence of fits of epilepsy and apoplexy in a patient within a short time of each other is not unheard of, yet without doubt it is rare enough to put on record as a case of some interest.

On the evening of December 18, 1879, I was called to see a man who had just had a "fit." The messenger described the man as having fallen suddenly, and, to use his own words, "foamed at the mouth and rastled about in the snow for as much as ten minutes." Thinking there could be no doubt but that it was an ordinary epileptic fit, the messenger was given twenty grains of bromide of potash to give the patient. Following the messenger to their camp in fifteen minutes, I found, upon entering the tent, that the patient was sitting on the bed, in a half-dazed condition, as epileptics are apt to be just after an attack. His pulse was sixty-four per minute, soft and full; the pupils were dilated. He complained of nothing, but, on questioning, said he had a sense of fulness in the top and front of the head.

While talking to him his face flushed, and he complained of feeling dizzy, and shortly afterward said he felt a numbness over the whole right side. This remark did not strike me at the time. The idea that it was *petit mal* being uppermost, he was given another dose of bromide of potash. In about an hour word came that the man was a great deal worse. On visiting him immediately I found him unconscious; pulse, twenty a minute, very weak and

* Brit. Med. Jour., September 27, 1879.

irregular; respiration about twelve, and of that peculiar puffing which is so characteristic of apoplexy. The pupils were contracted and immobile. I gave him a hypodermic injection of one cubic centigramme of fluid extract of ergot with one-fourth of a grain of morphia sulphas, and left directions that, *if* he recovered enough to swallow, he was to be given a drachm of the fluid extract of ergot every two hours.

On account of the man's condition and surroundings, I never expected to see him alive again. It was no little surprise the next morning to hear that he was not only not dead, but very much better. At ten o'clock A.M. he was conscious, pulse 80 and regular, paralysis of the right side marked, but not profound. No pain, but a tingling sensation over the whole right side. He was removed to an A-tent and given fluid extract of ergot in drachm doses three times daily for a week. The improvement was marked and continuous, and recovery was complete. He was able to sit up on Christmas day, and left camp on January 8, 1880.

Previous to this attack he said he had about fifty epileptic fits, but never had anything like apoplexy. He had never had syphilis or rheumatism, and had never been a drunkard.

This case is another illustration of how some men will recover from serious troubles under the most unfavorable conditions. To be sick in a tent during a ten days' winter storm, with the wind from twenty to thirty miles an hour, and the mercury — 20° F., surely speaks of vitality and recuperative powers little short of miraculous in the man who recovers.

CAMP ON SNAKE RIVER, WYOMING.

## A CASE OF POPLITEAL ANEURISM,

SUCCESSFULLY TREATED BY MEANS OF ESMARCH'S BANDAGE AND DIGITAL COMPRESSION.

BY E. Z. DERR, M.D.,

U. S. NAVY.

THE patient, a strong, robust man, was admitted to the U. S. Naval Hospital, Norfolk, Va., on April 15, 1881. Examination revealed the existence of a large, pulsating tumor in the left popliteal space. The calf of the leg was very much larger than its fellow, and both sensation and motion were very much diminished. Owing to this condition of things, no active surgical interference was resorted to until June 10th, when Esmarch's bandage was applied, and allowed to remain on forty-five minutes. At the end of that time the pain became so intense that it was removed. Pulsation returned after the removal of the bandage, but its force was perceptibly diminished.

On June 16th another application of the bandage was made, and allowed to remain one hour and twenty-five minutes. Pulsation returned on the removal of the bandage, but its force was still further diminished.

On July 9th the bandage was again applied, and allowed to remain one hour. At the same time digital compression was made over the femoral, and continued for six hours after the removal of the bandage. Pulsation returned after the cessation of the pressure, but was greatly diminished, and the tumor was found to be much smaller and firmer.

July 10th.—Digital compression was continued for two hours, causing still further diminution in the size of the tumor.

July 11th.—Compression was continued for three hours to-day, with further good results.

July 12th.—The compression was kept up for five consecutive hours to-day, and on the removal of pressure no pulsation could be detected.

At the present writing—September 9th—a hard, fibrous mass, not larger than a walnut, occupies the site of the large, pulsating tumor which previously existed.

I report the case because it furnishes another illustration of the utility of the combined method in the treatment of popliteal aneurism.

# Reports of Hospitals.

## BUFFALO GENERAL HOSPITAL, BUFFALO, N. Y.

SERVICE OF CHARLES C. F. GAY, M.D.

GUN-SHOT WOUND OF THE CRANIUM; A NO. 32 BULLET LODGED IN THE BRAIN FOR SIXTEEN DAYS—ITS REMOVAL—RECOVERY.

(Reported by C. C. Fredericks, M.D., House Surgeon.)

ANTONIO MUNCIATIO, aged forty-two years, was shot by George Nerone, on May 1, 1881, and on the same day was brought to the hospital. The ball penetrated the skull at the left parietal eminence. The wound had been explored, and a probe passed to the depth of three inches in a downward and forward direction without reaching the ball. There was some hemorrhage.

Patient was conscious; pulse and respiration normal; there was no pain, and the pupils were of equal size.

As no serious symptoms of brain lesion were present, it was thought advisable to wait for them to develop before resorting to an operation. During the first ten days, no bad symptoms showed themselves. On May 12th, cerebral symptoms became manifest; patient began to get dull; there was loss of appetite and some delirium at times. On the 16th, he became quite delirious; serum and pus have been escaping from the wound for the past three or four days; there are no symptoms of paralysis; pulse, which has been normal, now became slow.

| | Pulse. | Temperature. |
|---|---|---|
| May 14..... | 36 | 99° F. |
| May 15..... | 64 | 99¼° F. |
| May 16..... | 60 | 97¼° F. |
| May 17..... | 60 | 98¼° F. |

May 17th, the patient was etherized, and Dr. Gay cut down upon the skull, laying back a V-shaped flap. A circular opening through the skull was found, which had as clean-cut edges, and formed as perfect a circle, five-eighths of an inch in diameter, as though made with the trephine. A dozen pieces of comminuted bone were removed, some of which were lodged in the brain, one piece at a depth of three-fourths of an inch.

These pieces of bone removed, careful search was made for the bullet, which was found imbedded one inch beyond the surface of the brain. It was brought out to the orifice by means of a blunt strabismus hook. The ball was flattened and too large to pass through the orifice, until the orifice had been enlarged by means of the rongeur. There was no hemorrhage; the wound was dressed, and stimu-

lants and tonics freely administered during the following three or four days. The pulse, after the operation, rose to seventy-two per minute.

| | Pulse. | Temperature. |
|---|---|---|
| May 18..... | 70 | 97¼° F. |
| May 19..... | 70 | 99¼° F. |
| May 20..... | 104 | 100⅝° F. |
| May 21..... | 100 | 98° F. |
| May 22..... | 90 | 98° F. |

The right pupil is observed to be a little more dilated than the left, the latter is normal.

Tonics and stimulants were discontinued and fl. ext. apocynum cannab., gtt. xv. ter. die, ordered.

May 24th.—All medicine discontinued. Patient much improved, there is no delirium; pupils normal. Slight paralysis is noticed in right hand, which may have existed for days unobserved, it is only now apparent by patient's inability to forcibly flex the fingers.

May 25th.—The patient seems entirely to have recovered, and is only awaiting closure of the wound. Pulse, 90; temperature, 98. He is allowed to be up and dressed.

June 18th.—Left hospital and has engaged in his usual occupation, and has continued well up to the date of writing this report, August 23, 1881.

## ST. MARY'S HOSPITAL, LONDON.

UNDER THE CARE OF DR. HANDFIELD JONES, F.R.S.

### ANEURISM OF THE ABDOMINAL AORTA.

W. M——, aged forty-seven, married, shopkeeper, is one of a large family, many of whom died in infancy. The patient says he had an attack of "bilious fever" when in America, seventeen years ago, and after that "typhus fever." While recovering from the latter he was attacked by ague, and has had several attacks subsequently until he returned to England, eleven months ago. He had a slight attack of ague last winter. He also contracted gonorrhœa last winter, and says he had a sore on the penis at the same time, but has never had any other symptoms of syphilis. With these exceptions, he has always enjoyed good health.

The present illness commenced on August 20, 1881, with a slight attack of ague, for which he attended at St. Mary's Hospital as an out-patient on August 25th. At the same time he felt "rheumatic" pains about the left hip. He first noticed a lump on that region the day he came to the hospital. On examination a pulsating tumor was found in the left lumbar region the size of a large orange. It occupied the space between the lower ribs and the iliac crest, and extended from the axillary line in front to about an inch and a half from the posterior median line. It was not painful or tender, and on percussion was completely dull. The pulsation was not expansile, but took place *en masse*. On pressing deeply on the abdominal wall in front on the left side a hard substance was felt with a well-defined inferior border. It was covered by intestine, and extended from the lower border of the thorax to about two fingers' breadths above the level of the iliac spines. It was not tender. The heart-sounds were normal.

The patient was admitted on August 29th. His aspect was then natural, and he expressed himself as feeling well in himself, and as not suffering any inconvenience from the tumor. He slept well, and took his food well. Pulse weak. The urine was slightly smoky, specific gravity 1,035, and no albumen, but contained iodine. As his bowels were confined, a purgative pill and an enema were administered. He was put upon "broth diet" with milk and beef-tea, but the quantity of liquids given was restricted to one pint in twenty-four hours. Iodide of potassium was given internally (fifteen grains three times a day).

During the next few days the tumor remained about the same. Ice was constantly applied to it.

August 8th.—Complains of pain in left inguinal region and has flatulence. No change in the tumor. Ice discontinued and an antacid mixture given for flatulence. Urine presents the same characters. The next day he complained of "rheumatic" pains in left hip, for which a belladonna liniment was ordered.

August 12th.—Has had a very restless night, with flying pains in spine. Severe, darting pain in lumbar region of spine came on about 8 A.M., and lasted an hour and a half. There is some swelling in left groin, with numbness and much pain. Pulse, 100; temperature, 99.6° F. His tongue is furred, and appetite bad. Tumor larger and firmer.

August 13th.—More feverish. Temperature rose to 100° F. in evening. Morphia is given to relieve the pain.

August 15th.—Has had no sleep, owing to constant pain over stomach and bowels. To-day M. de Watteville passed two needles into the tumor, and a galvanic current was also passed. The needles did not move freely in the tumor, but seemed firmly held. There was no apparent change in the tumor after the operation.

August 18th.—Tumor again galvanized, without any apparent result.

August 22d.—Feels pretty well to-day. Occasional slight pains in back, which come and go. Temperature varies from 97° to 99.6°, the latter being highest recorded within the last few days.

September 1st.—Passed a good night, but complained of sickness in morning.

September 2d.—No pain. Perspires freely after taking morphia. Two grains of zinc sulphate to be given every night.

September 3d.—Patient complained, about eleven o'clock, that pain in tumor had returned. On examination it seemed firmer, more tense at middle than at sides, and seemed moving round toward back.

September 5th.—Not in pain. Eight grains of zinc chloride injected into tumor.

September 7th.—Patient suddenly called out, at 6.30 A.M., that tumor had grown as large as his head all at once. On being examined, it appeared much increased in size, and more so posteriorly and inferiorly. It is becoming purple, especially at its summit. Patient has great pain between scapula, extending down spine to the tumor. He cannot bear to be touched over site of pain. Morphia injected.

September 8th.—Tumor seems increasing in size; is markedly discolored in two places. Pulsations very violent, and plainly visible. Evening temperature, 100° F.

September 9th.—Patient is in continual pain. Calls for morphia directly he wakes up. Tumor about the same. Temperature normal.

September 14th.—The patient died early this morning.

*Post-mortem* (September 15th).—The tumor was found to be a large aneurism of the abdominal aorta, which almost entirely filled the left side of the ab-

dominal cavity, displacing the left kidney downward. The cavity of the aneurism was almost entirely filled up by coagulated blood, very firm, and in concentric layers, only a small central channel being left.

*Remarks.*—When the patient was first admitted, Dr. Handfield Jones expressed the opinion that the tumor was an aneurism. As the case progressed, however, suspicions were entertained that it might prove malignant—in which opinion Mr. Norton, who also saw the case, coincided. The case illustrates the difficulties attending the elucidation of the nature of abdominal tumors.

## Progress of Medical Science.

REDUPLICATION OF HEART-SOUNDS.—The following case of asynchronous contraction of the cardiac ventricles has been reported by Dr. Frederick P. Henry, in the *Archives of Medicine*, July, 1881: The patient, a multipara, aged thirty-four, had had eight attacks of articular rheumatism, the last one three years ago, at which time her heart-trouble began. There was no œdema; respiration, in the recumbent position was tranquil; urine free from albumen. There was a distinct mitral regurgitant murmur, and also what appeared to be a very irregular action of the cardiac muscle. The pulse was forty-eight per minute, and over the heart's apex could be counted ninety-six distinct pulsations, succeeding each other at regular intervals, and each apparently composed of a complete cardiac revolution. The cardiac sounds were four in number, the first accompanied by a murmur loudest at the apex; and their rhythm was irregular, the first two and last two succeeding each other more rapidly than did the second and third; that is to say, there was a distinct pause between the separate action of the ventricles, but decidedly shorter than the regular pause occurring at the close of the complete revolution. The intensity of these sounds also varied in degree; the first and third, however, namely, those due respectively to the closure of the mitral valve and the contraction of the left ventricle, and to the closure of the tricuspid valve and the contraction of the right ventricle, being nearly equal in intensity. The patient improved somewhat under treatment, but subsequently she suffered a relapse with very urgent symptoms, and, at her own request, was discharged from the hospital.

There are three principal means by which reduplication of cardiac sounds may be produced. The first, most common, and best understood, is the asynchronous closure of the aortic and pulmonary valves, and is not a very rare phenomenon. It occurs both physiologically, as has been shown by Potain, and in disease when, from any cause, the normal ratio of aortic and pulmonary tension is destroyed. This asynchronous closure of the semilunar valve gives rise to the *bruit de rappel* of Bouillaud, and, inasmuch as it is composed of a long sound followed by two short ones, it has been called a dactylic sound, and may be represented by the usual symbol for the dactyl, — ⏑ ⏑. The second principal course of the reduplication of cardiac sounds is due to an abnormal action of the left ventricle, giving rise to the *bruit de galop*, also first recognized and named by Bouillaud, but afterward more minutely studied and described by Potain. From its resemblance to the foot of Greek and Latin metre, known as the anapest, it has been spoken of as an anapestic sound, and may be represented with considerable accuracy by the usual symbol for the anapest, ⏑ ⏑ —. The extra heart-sound which gives rise to the *bruit de galop* is presytolic, and it has been demonstrated as a movement by Potain by means of his cardiograph; and the same observer has shown that the movement is the distention of the ventricle, accomplished and completed by the contraction of the auricle. Potain shows in confirmation of this view that the presytolic movement coincides with the jugular venous pulse constantly encountered in these cases. Potain considers this abnormal sound to be so high in the scale of diagnostic importance, that occasionally it may call attention to the existence of an interstitial nephritis that might otherwise continue unsuspected. Dr. Henry, on the other hand, regards it as of about as much diagnostic value as the retinitis nephritica, of which oculists were wont to talk so much in the first flush of their discovery, and of which so little is said to-day.

Dr. Henry suggests that the sound produced by the asynchronous contraction of the ventricles be spoken of as a double iambic sound, and that it be represented by the symbol of the double iambus, ⏑ — ⏑ —, and, in so doing, he refers to the sound independently of any murmur that may be associated with them. In the only two cases with which he is acquainted, Leyden's and his own, there was valvular disease, of rheumatic origin, giving rise to one or more murmurs. There is one form of valvular disease which, he thinks, entirely prevents the *bruit de galop*, namely, mitral obstruction. The first sound of the *bruit de galop* is due to a diastolic pulsation of the ventricle, caused by an abnormally energetic contraction of the auricle in the presystolic period, and in order that the auricular contraction may have full effect, the mitral orifice must be unobstructed. This is not said unadvisedly, for in a case of mitral obstruction that was under his care about two years ago, the left auricle had become so hypertrophied that its pulsation could be distinctly felt, and aneurism was at first suspected. This was readily excluded, and mitral obstruction immediately diagnosticated. Notwithstanding this abnormally powerful action of the left auricle, there was never detected the slightest diastolic pulsation of the left ventricle.

PULMONARY GYMNASTICS; OR, FORCED RESPIRATION IN THE TREATMENT OF SO-CALLED WEAK LUNGS, ATELECTASIS, PHTHISIS, ETC.—Dr. T. C. Smith describes (*Medical and Surgical Reporter*, June 25, 1881) the so-called "weak chest" as a condition observed among those confined closely at their labors many hours in the day, and who take little or no active exercise. These patients complain of general weakness, dyspnœa after moderate exercise, a feeling amounting to soreness, or dull pain within the lungs, perhaps dull intercostal pains. Attending these symptoms there is often general lassitude and melancholic expression. Physical exploration may not, and very often does not, develop any evidence of disease of the lung-tissue. If in these cases there is any hereditary tendency to phthisis, the gravity of the symptoms is increased, and, unless overcome, will be likely to lead to serious results. Dr. Smith's attention was called to this condition by the case of a young student who was of healthy physique, good habits, and of healthy parents. He complained of dyspnœa on slight exercise, pain in the chest, of

intercostal pain, had dry, troublesome cough, general lassitude, and disposition to melancholia. He improved under tonics and good diet and out-door exercise, but the pulmonary symptoms were the same. He was then directed to make deep and prolonged inspirations and forced expirations many times every day, after the following method: having placed a small tube between his teeth—a common quill or toothpick answers very well—he was ordered to breathe exclusively through this, both by inspiration and expiration. About every third respiration he was directed to quietly withdraw the tube, when the lungs were thoroughly filled, and to hold his breath as long as he could without distress. This simple process was to be repeated six to eight times every twenty-four hours, and he was to take a dozen deep inspirations in this manner at each time of repetition. He at once experienced relief, and rapidly improved in general health. Physical examination at no time showed any real disease of lung-tissue in this case. This young man continued to practise this during his years of student-life, and acquired the ability to effect a difference of five inches in the measurements of his chest, as between forced expiration and inspiration; and could, after taking a few deep inspirations, hold his breath for a full minute without distress.

It is not claimed that this will cure phthisis in its early stage, but it may be made a valuable means of relief in connection with other remedies. It will often be found that, in many cases where a condition of atelectasis is present from bronchial catarrh, or following lobular pneumonia, forced inspiration will be the means of opening up the closed bronchial tubes and air-cells sufficiently to cause a removal of the trouble. By this means the decomposing debris of detached and locked-up epithelium can be removed, and the diseased lung-tissue treated to the pure air needed to restore it, through reparation, to a condition of health. Where the thickened mucous membrane of the diseased bronchia causes atelectasis of any portion of the lung, forced inspiration will often open this up, and the collapse of lung-tissue will disappear, or enclosed foul air will be exchanged for that which is pure and wholesome.

It may be remembered that Dr. P. Niemeyer several years ago recommended a very similar course of pulmonary gymnastics for precisely similar conditions of so-called "weak chest."

Ovaritis.—Prof. Vedeler, in a paper read before the Christiania Medical Society, says that as the inflamed ovary is irritable and larger than normal, and, as a rule, dislocated and fixed, it is easier to feel than the normal one. The ease with which the normal ovary may be felt, is, according to the author, quite variable; it may be most readily done in lean multipara, where it is found as a flat, readily movable, insensible body, about the size of an almond, perhaps an inch to the side of the fundus uteri. The size of the inflamed ovary is, in the ordinary forms, about that of a common apple; in chronic cases, that of a walnut, chestnut, or (most frequently) an almond-shell; the surface is generally smooth, the consistence elastic. In the larger ovaries the author was able to feel distinctly small elevations, supposed to be inflamed and hypertrophied follicles. The dislocation is due to the increased weight of the organ, but the degree may depend on accidental anatomical conditions, for a somewhat large ovary may be situated relatively high up, while a much smaller one may rest on the bottom of the fossa Douglasi. As the inner end of the ovary is fastened to the uterus by the ligamentum ovarii, while the other is quite movable, the inflamed and longer ovary will fall downward and inward, and the ligamentum ovarii will contract on account of the inflammatory conditions. The ovary is, therefore, nearer the uterus than usual. The cause of the greater or less immovability is probably new-formed perimetritic adhesions. There is usually considerable tenderness, and generally, during an examination, a certain sensitiveness in one or another portion of the vaginal arch attracts our attention. If the index finger is now introduced as far as possible, the surface of a little tumor is suddenly felt. Combined examination by the rectum makes the case plain. An ovaritis is often overlooked in the presence of a complicated uterine disease, the latter being more apt to attract the attention. The author does not believe that a heavy and inflamed ovary causes retroversion, since he found but fifteen retroversio-flexions in fifty cases of ovaritis. Ovaritis has no subjective symptom which is pathognomonic; manual examination is, therefore, absolutely necessary. Most frequently there are pains in the iliac region, shooting down over the thigh. Ovaritis causes a tendency to dysmenorrhœa, though the latter is by no means stubborn. Menorrhagia and metrorrhagia are not rare. Amenorrhœa was not met with as a symptom of ovaritis. Nausea and vomiting were only occasional complications of the chronic forms; in acute cases they were due to the fever. Hysteria was found in five cases out of fifty, but in none of these could a hysterical access be excited by manipulation of the diseased organ. Interstitial neuralgia was not rare. In all the fifty cases, with the exception of one (where there was marked hysterical vomiting), the general condition was satisfactory. Over thirty per cent. were sterile.

*Etiology.*—Over-exertion is not regarded as a probable cause, though it may be an occasional one. Gonorrhœa is undoubtedly the most frequent cause, acting by direct continuation from the vagina through the uterus and tube to the ovary. Gonorrhœa was found to be the cause in thirty-eight per cent. of the cases. The recognition of this cause is often difficult, as the symptoms of gonorrhœa disappear from the external sexual parts when the ovaritis appears, in exactly the same manner as epididymitis; and there is not always an opportunity to examine the husband. Suppression of the menses, excessive coitus, rheumatic and exanthematic fever were not met with as causes, though it is not doubted that exanthematic and septic fever may produce an endometritis with a further continuation. In eighteen of the fifty cases no cause could be found.

*Termination.*—Cirrhosis was not met with in the living, though it could be demonstrated post-mortem. Termination in ovarial abscess was met with once. Peritonitis followed. On section the ovary was found to contain a number of communicating cavities filled with pus, one of which opened into the peritoneal cavity. Restitutio ad integrum is not frequent; the course is usually chronic, with exacerbations and remissions, and as the pain is rarely great, and the influence on the general condition little or nothing, the patient gradually passes out of notice.

*Treatment for acute ovaritis.*—Neptune's belt, leeches to the vagina, saline cathartics, quinine, opium till every trace of tenderness has disappeared and the ovary can no longer be felt. Vedeler was unable to decide as to the merits of gold salts, which

Noeggerath regards as specific. Chronic ovaritis is difficult to cure, and relapses readily occur. Among internal remedies, most benefit was obtained from bromide of potash and ergotin combined, and given in pills. Externally, turpentine to the abdomen, after which a Neptune's belt was left on all night, and a woollen bandage was worn over the abdomen through the day. Leeches were used at the commencement of the treatment, and later on when there was great tenderness or pain. Generally two were applied to the vaginal arch on the diseased side. Every other day the vaginal arch was pencilled with superiodide of potash. A suppository of equal parts of opium and extract of belladonna was placed in the vagina every evening.—*Norsk Mag. f. Loegevidenskaben* and *Nordiskt Med. Arkiv*, vol. xii., No. 27.

Aphthongia.—This was the name given by Fleury, in 1865, to a variety of aphasia characterized by spasm of the muscles supplied by the hyperglossal nerve whenever the patient attempts to speak. In Mossdorf's case (*Chl. f. Nervenheilk.*, No. 1, 1880, and *Arch. de Neurologie*, No. 2, 1880), when the patient, a boy aged seventeen, attempted to speak, the hyoid and abdominal muscles became cramped, respiration ceased, and through the half-opened mouth the tongue was seen contracted, its tip firmly pressed against the lower incisors, and its dorsum against the palate. In a few moments the abdominal muscles relaxed, and respiration was resumed, but the spasm of the tongue and hyoid muscles persisted. The movements of the tongue, lips, and face were, with this exception, quite normal. Latterly the boy was unable to reply to his parents, or even read aloud when alone. The difficulty of speech showed itself when he was six years old, and was attributed to fright. A cure was effected by galvanization: the negative pole was placed in the nape of the neck, and the positive pole slowly moved up and down the spine.—*Brain*, July, 1881.

A Case of Leprosy of the Larynx.—Dr. George Mackern (*Lancet*, July 23, 1881) has reported a case of true leprosy of the larynx, which came under his observation during his recent travels in upper Egypt. He was accosted by a beggar by the roadside, who demanded "backsheesh" with such a peculiarly hissing sound of voice, that the doctor stopped to examine him more closely. He was a Syrian, aged forty-two years, and had been ailing for six years, but had developed leprosy during the last four years only. The leprous tubercles appeared early in his illness; first in his face and hands, subsequently in both groins, and more recently along the dorsum of his tongue. The tubercles developed slowly and showed but little tendency to ulceration. He never suffered from itching, but complained of loss of sensation in the parts affected. During the last few months he had rapidly lost his voice, phonation being accompanied by a peculiar hissing sound. Previous to this his tongue had become affected, and his nose also became clogged up, interfering with his breathing. He was old and haggard in appearance; on both sides of his nose and cheek there were a number of smooth, rounded and hard tubercles of yellowish brown color; a few were also present at the anterior nares; one or two only were ulcerated, the rest being either quite smooth and shining, or covered with a branny desquamation. Tubercles of a like description were present in both groins and on his hands, on the palmar and dorsal surfaces, but the feet appeared free, although the inner and upper part of the thighs showed tubercles and ulcerations. His tongue presented a remarkable appearance. Along its dorsal aspect it was ridged and furrowed by the disease, tubercles as large as peas and of a distinctly yellow color forming its ridges, and the furrows being formed by ulcerating surfaces.

The fauces were free from tubercles, but the epiglottis was a typical example of the disease as manifested in the larynx. It was enlarged and much thickened; its edges were quite rounded and curled in toward each other; the whole was of a pale grayish color, and along the upper convex margin on the left side were seen three tubercles projecting from the surface, and of a yellow color, one especially being of a bright orange color. No ulceration was observed anywhere in the epiglottis. On testing with the laryngeal probe, the whole surface of the epiglottis was found to be perfectly anæsthetic, no reflex action or cough being produced. In consistence the epiglottis was firm to the touch, giving the idea of an infiltration with some dense material. It was impossible to see well into the larynx, owing to the size and shape of the epiglottis.

The above description agrees closely with that given by Virchow, and with the first two cases recorded by Mackenzie. But in this case distinct tubercles in the epiglottis and complete anæsthesia of that part was observed, a point not hitherto described.

Traumatism in Syphilitics.—Folinea (*Archives Générales de Médicine*, July, 1881) regards syphilis as a means of transforming wounds of traumatic origin into specific manifestations, especially during the inflammatory period. The transmission may take place during the active period of syphilis, whether there be syphilitic manifestations near or at a distance from the wound. The initial lesion has no influence on wounds at a distance from it. During the active period of syphilis, when the disease does not transform traumatism into syphilitic manifestations, it causes them to assume an indolent type, incurable except by anti-syphilitic treatment. During the latent intervals of the secondary period, syphilis acts as if it were in activity, whether in causing the traumatism to take on a syphilitic type or in retarding recovery, unless specific treatment be used. Latent syphilis, during the neoplastic period, has but seldom a specific action on traumatisms. Wounds are almost always unaffected by the coexistence of syphilis. Traumatic lesions in syphilitic subjects can be the source of syphilitic infection, and in patients suffering from latent or active recent syphilis can become the point of departure for new syphilitic manifestations. A traumatic lesion in a non-syphilitic subject, who subsequently becomes infected, may become the point of departure for all the manifestations of syphilis.

American *v.* Arabian Horses.—We do not believe the Arabian horse to be superior to the American or English thoroughbred in either speed or endurance, and have no doubt that the best American or English horse can concede the best Arabian two stone, and defeat them over any distance of ground. The Arabian horse cannot be used for forty-eight consecutive hours without water. The Arabs stint their horses of water; they conceive and justify this course by their belief that much liquid injures the horse's shape and impairs his wind.—*Mobile Item.*

# THE MEDICAL RECORD:

## A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, October 29, 1881.

## REGULATING THE PRACTICE OF MEDICINE.

Such as are interested in laws for regulating the practice of medicine in different States will receive with becoming discouragement the announcement that "the law of 1880" of this State is practically a failure. The Board of Censors of the Medical Society of the County of New York have made their first annual report concerning the working of the law and the results of prosecution for its infringement, and base their unwelcome verdict regarding its utility upon the stubborn facts of a sufficiently extensive experience before the grand jury and in the police courts.

It appears to be conceded by the gentlemen of the committee, as well as by the distinguished counsel for the society, Mr. E. C. Ripley, of this city, that the law is deficient in many important particulars. For instance, it has been proven that any person can register without a diploma and yet escape conviction of the charge of perjury. The District Attorney has expressed the opinion that such false swearing is not perjury, in the strict sense of the term, and cannot be punished as such according to the provisions of the law of 1880. Such an opinion, if sustained, breaks the backbone of the law, and makes the latter virtually a dead letter. In view of this being possible, it would appear to be unwise, in any future amendment of the law, to allow any latitude whatever to an individual registering, and to hold him to the strictest accountability for the slightest misconception of his privileges. How this can best be done must be a subject for careful study. In the attempt to frame such a law the danger will be in dodging between the charge of class legislation on one hand, and an undue leniency toward quackery on the other. It is well known that while the framers of the law of 1880 were honest in their intentions, they had to submit, by way of compromise, to the tinkering of legislators more or less directly connected with patent medicine schemes and other systems of quackery. The result is now obvious. Not only is the present law ineffective, but its enactment has rendered null the provisions of former laws on the same subject. The latter fact must be taken into consideration when the time arrives for amendments to be made.

The suggestions from the committee regarding the practicability of State examination comes with a renewed force after the experiences of the past year, and must command attention accordingly. There are many conditions to be taken into account before the desirable end can be reached, but we are convinced that such is the only way out of the present difficulties in applying a law to supply the real needs of the public, and meet the requirements of lawful medical practice.

### THE ADIRONDACK CURE FOR PHTHISIS.

Under the stimulus of an ill-advised magazine article, the Adirondack region was widely invaded by phthisical patients last summer. We now hear from all sides complaints that very little good was effected there; that many persons died in the woods; and that many others received absolutely no benefit. The impression is abroad that the "wilderness cure" is a failure.

The Adirondack region was first prominently advocated as a health resort by Dr. A. L. Loomis, in a very temperate and able article that was published in this journal. The author disclaimed a belief in any specific "climate cure," and asserted for the Adirondacks only that it had pure air, and a dry, well-drained soil as its most conspicuously beneficial qualities. No special stress was laid upon the evenness of the temperature or the dryness of the air. He presented twenty cases, as illustrating the effects of the locality upon phthisis. Of these twenty, ten recovered, six were improved, two not benefited, and two died. The cases cured were of the catarrhal form of phthisis, the disease in most of the cases not having reached the stage of excavation.

Of the six patients who were benefited, four had catarrhal and two fibrous phthisis. The two cases not benefited were of the tubercular form, while the fatal cases were far advanced in catarrhal phthisis. Dr. Loomis's observations tended to show that it was in certain forms of catarrhal phthisis that benefit or cure was to be expected. Fibrous phthisis would, he thought, do better in Colorado. Tubercular phthisis and some of the catarrhal forms could not be expected to improve anywhere.

Now this presentation of the wilderness cure is very different from that of the enthusiastic, but very unwise gentleman, who, having cured himself in the Adirondacks, "wrote up" the wilderness in most glowing colors.*

* The Wilderness Cure. By Marc Cook. New York: Wm. Wood & Co. 1881.

It is no wonder that many bitter disappointments followed to those who caught the hopeful spirit of the book's work. Perhaps even medical men were a little affected by it. Otherwise, it does not seem possible to explain the many phthisical invalids, entirely unfit for camp life anywhere, who swarmed into the St. Regis region, there to die. Instead of the wild and peaceful beauty of the forest, they found rain, cold, poor food, and discomforts of all kinds. And instead of quiet and rest, they heard the hacking coughs and met the wan forms and haggard faces of others struggling like themselves for a further lease of life. Some patients died almost as soon as they arrived, and there was the depression of the funeral instead of the exhilaration of healthful life which the primeval forest was expected to suggest. So far as food and the various comforts of life are concerned, as well as regards the pleasantness of the weather, invalids last summer were, we learn, much disappointed. This was due in part, perhaps, to its being an exceptionally disagreeable season.

On the whole, the lessons of the history of this resort are chiefly those of prudence for the future. The wilderness cure has not yet proved a failure, but it is proved that the class of cases who may be benefited there must be carefully selected ones. We may in time learn that the Adirondacks are no better than almost any other mountain resorts; but definite opinions must be based on statistics not yet obtainable.

It may be well to remember, however, that cold and high altitudes for phthisis are just now in fashion. There is a degree of reaction from the older practice of sending every one to warm climates, like Madeira, Egypt, Florida, etc. On the other hand, Davos and the Upper Engadine are among the most popular resorts in Europe for the phthisical, while Colorado, which is warmer but equally elevated, is proportionately popular in this country. Several years ago, Dr. James Henry Bennett expressed his disbelief in these places, and advocated a temperate climate as the most efficacious and most rational form of "climate cure." It remains to be seen whether his opinions will not ultimately prevail.

---

### PRIZES OFFERED BY THE FRENCH ACADEMY.

We published not long ago a list of some of the large prizes which were offered for competition by foreign societies or universities. It is instructive to be reminded once in a while how much better they do things elsewhere than in America. And we are tempted to refer to this particular matter of our inferiority in the matter of offering prizes, by seeing the recently published list, proposed for the year 1882 by the French Academy of Medicine, This list includes fourteen different sums, to be awarded for investigations in various departments of medical science. The largest amount offered is $5,000, the smallest is $250; there are two prizes of $1,000, one of $600, while the rest are about equally divided between prizes of $250, $300, and $400. The total amount thus offered is over $10,000.

The largest prize, that of $5,000, is one offered by M. and Madame Saint Paul, for the discovery of a specific against diphtheria. It is open to any person of any nation. It is wisely arranged that, pending the discovery of this specific, the interest on the money shall be used to encourage researches upon the subject in question, and is to be bestowed biennially upon such person as has made a noteworthy contribution to the knowledge of diphtheria. It is an interesting fact that two of the other prizes are given by women.

In about half the cases, the name of the subject upon which the competing thesis must be written is given. Thus the Academy prize is upon general arterial atheroma and its influence upon the nutrition of organs; that of the Baron Portal is upon the lymphatic system in its pathological relations. Locomotor ataxia, and the hygiene of infancy have also been selected as subjects for competitive study.

In the three large Eastern medical centres of this country, New York, Philadelphia, and Boston, there are about half a dozen prizes offered altogether. The total sum does not, we believe, exceed, if it even reaches, one thousand dollars annually. But a fact which is even more unpleasant than this one, is that we Americans do not get all the prizes that are offered us. Twice has the Boylston prize been carried off by Englishmen. It is not at all rare for some of the prizes offered in this city to be allowed to go unbestowed, because there has not been a sufficiently good essay put in competition. If we need therefore more prizes, we also need persons who can take them when they are offered.

All of which brings us round to the threadbare topic of the comparative barrenness of American researches in the field of medical science. Upon this we forbear to comment. It is a defect which will be corrected in time. Meanwhile we have to consider whether this time cannot be hastened by the offering of more prizes or the endowment of chairs for scientific and medical work.

---

### A GOVERNMENTAL VETERINARY BUREAU.

The project of establishing a national veterinary bureau, which was discussed in The Record some years ago, has recently been revived. The continued existence of pleuro-pneumonia, and foot-and-mouth disease in American cattle, the large mortality from hog-cholera (infectious pneumo-enteritis), the embargo put upon American pork because of possible trichinæ, and upon American cattle because of pleuro-pneumonia, all these things have had a tendency to show the need of some central supervision over the sanitary condition of our domestic animals.

In addition to this the frequency of epidemics of

splenic fever among cattle and of dangerous influenzas among horses show that we need more than local studies in order to understand and prevent these diseases. The possibility of contagious pleuropneumonia being carried into Western herds still exists, and thereby greatly endangers the cattle interests.

Appreciating the need of some investigation concerning these various contagious diseases, the Treasury Department has appointed a commission to examine into them. This commission has been at work during the past summer, and is still engaged in accumulating facts upon the matters which it has been authorized to investigate. Its members are capable men, and no doubt will render much useful service.

But this commission is only a temporary affair, engaged in investigating certain specific questions. It does not at all serve the purpose of a national health bureau.

It is asked, therefore, among sanitarians, veterinarians, and stock-breeders whether such a bureau shall not be established. At a meeting of the Farmers' Club of this city, not long ago, a resolution approving such a board was passed.

Despite all the arguments there and elsewhere advanced, however, we are inclined to adhere to the view expressed when this matter first came up, that the creation of any separate national health bureau would not be judicious.

It would be, however, a prudent policy to establish some kind of central office at Washington, either in connection with the National Health Board or with the Agricultural Department; preferably the latter. Through the medium of regularly appointed inspectors or correspondents such an office could obtain authoritative facts regarding the prevalence of contagious diseases. These, published in official bulletins, would have a weight which no private or press reports could receive. By such means the damage to our commerce and agriculture caused by foreign embargoes on American cattle or meat could be prevented.

Investigations into the nature of diseases and contagions would also necessarily be made. Thus both pathological science and our financial interests would be promoted.

A central veterinary bureau of some kind is an object of such palpable utility that its establishment can hardly be anything but a matter of time. But there is no need of anything so pretentious and cumbersome as an independent national board.

---

### THE ANNUAL REPORT ON HYGIENE.

The presentation of the annual report of the Committee on Hygiene, of the Medical Society of the County of New York, will serve as a reminder to the profession of the great interest taken in sanitary reforms by this organization, and of the persistency with which work in the desired direction has been prosecuted. While not desiring to make invidious comparisons, it is but justice to say that the principal part of the labor of the committee has been performed by its indefatigable chairman, who through evil as well as good report has lost no opportunity of advocating the necessities for reform in street-cleaning, the proper disposal of garbage, and the effectual abatement of nuisances. In all this he has been ably assisted by other members of the committee, and has received the sanction and endorsement of a powerful medical organization.

It is gratifying to learn that the work thus conscientiously performed, has not been in vain, and that reasonable progress has been made toward bringing about the needed reforms. Our streets, although susceptible of much improvement, are in a more cleanly condition than has been the case for many years past. This result is in no small degree due to the Committee of Hygiene of the County Medical Society, and is an evidence of the influence which medical opinion is exerting upon the sanitary needs of a great city.

It is not necessary to follow the chairman of the committee through the details of work done by the Health Board, or give the statistics of the past year, as collated from the official bulletins, as such data have been from time to time duly presented to our readers, but there are some suggestions connected with such data as deserve consideration in this connection. For instance, the proper disposal of manure and the abatement of the stable nuisance in the city are questions which should interest every sanitarian, and which call for some direct and practical solution.

The suggestions of the committee regarding the substitution of sawdust or shavings for straw, and the packing of manure in barrels or other movable receptacles, are in the right direction.

As can be readily believed, fermentation and the attendant escape of malodorous gases can by such means be prevented. At the same time the transportation of valuable material for the farmer can be greatly facilitated. The groundwork of the argument against the present storing and ultimate disposal of manure is the fact that such processes are positively unhealthy; the ordinary stableman and cow-boy to the contrary notwithstanding. Evidently sanitary science has made some advances since the time when hostlers were considered its authoritative exponents.

It will be a matter of some surprise to many to learn that there are at present no meat-inspectors in this city, and that the reason of this is the lack of funds in the hands of the Health Commissioners. No argument is needed to enforce the necessity of appointing such inspectors at once, and of raising the requisite funds for the purpose.

Again, the recommendation to appoint engineers to see that the new plumbing bill be enforced is one of scarcely less importance. Although the results of such inspections are not, prospectively considered, very promising, the moral law enjoins upon all good citizens and sanitarians to curtail the privileges of the ordinary plumber so far as is practicable or possible.

But we cannot undertake to review every point in the elaborate and comprehensive report of the distinguished chairman of the committee, Dr. John C. Peters, and must be content by noting substantial progress made in many important sanitary matters, and encouraging ourselves with the good prospects of the near future. The society of the county has efficiently upheld the hands of its committee, and there is every encouragement to continue in the good work.

## Reviews and Notices of Books.

MANUAL OF THE PHYSICAL DIAGNOSIS of DISEASES OF THE HEART, INCLUDING THE USE OF THE SPHYGMOGRAPH AND CARDIOGRAPH. By ARTHUR E. SANSOM, M.D., London F.R.C.P., etc. Third Edition, 12mo, pp. 300. Philadelphia: Presley Blakiston. 1881.

DR. SANSOM'S practical little volume has for some years been considered, and justly so, the best work of its kind in the English language. This third edition of his book has been considerably enlarged by the addition of new chapters describing the methods of employment of that much neglected little instrument, the sphygmograph. The author claims that this instrument has already attained such mechanical perfection and diminution of original bulk, that in its present shape it should be found as frequently in the physician's pocket as the thermometer and hypodermic syringe. We fear the millennium for sphygmographs has not yet come, though its advent may linger in the near future. If the author carries out his intention of supplementing the present book by a volume on treatment of cardiac affections, and if the second part will prove as satisfactory as the first, we shall possess a systematic treatise on heart disease as concise as it is reliable, and as practical as it is complete.

A MANUAL OF HISTOLOGY. Edited and prepared by THOMAS E. SATTERTHWAITE, M.D., of New York, in association with Drs. Thomas Dwight, J. Collins Warren, William F. Whitney, Clarence J. Blake, and C. H. Williams, of Boston; Dr. J. Henry Simes, of Philadelphia; Dr. B. F. Westbrook, of Brooklyn; and Drs. Edmund C. Wendt, Abraham Mayer, R. W. Amidon, A. R. Robinson, W. R. Birdsall, Dr. Bryson Delavan, C. L. Dana, and W. H. Porter, of New York City. With one hundred and ninety-eight illustrations. 8vo, pp. 478. New York: W. Wood & Co. 1881.

A WORK which completely fulfils the objects that prompted its preparation, provided such objects be legitimate ones, merits the praise that belongs to all successful achievements. The volume before us very certainly deserves the general commendation implied in the above remarks; but, in addition, its special significance justly entitles it to something more than this, for the editor and those associated with him have assuredly earned the thanks of the entire American profession by the preparation of their volume. It has been generally supposed that histological research, and laborious studies incident thereto, could flourish only on European soil. Satterthwaite's "Histology," however, embodies the practical demonstration of the erroneousness of this view. Manifestly, no modern work on this fundamental and highly important branch of medicine can be quite original; but the volume before us at least attests the fact that American physicians are as well qualified for independent histological research as the scientists abroad.

Certainly, we still lack many of the European facilities for original work of this kind, and, above all, there is a lack of that general and intelligent appreciation of its practical value—an appreciation which supplies so vigorous a stimulant to the prosecution of microscopical studies in Europe. It is because we are so fully conscious of these very disadvantages that the excellence of the present work so agreeably surprised and pleased us. To be sure, we miss the uniform excellency of works prepared by a single writer, when that writer happens to be a master-mind; but, instead, there is a compensatory variety as regards style and manner of treating the different topics that make up the twenty-eight chapters of the book. This circumstance goes far to make it decidedly pleasant reading.

A prominent and valuable feature of Satterthwaite's "Histology" is the eminently practical nature of the information it contains. This is doubtless due to the fact that the editor and most of the contributors are themselves teachers of histology, and as such are fully alive to the needs of the student; but the manual before us will also be found serviceable to those who may wish to pursue histological studies independent of other tuition. The whole book has been wisely kept within moderate limits as regards its size. Thus, while it gives all the essential facts found in larger and more pretentious works, it is a far more convenient and handy volume for reference than any with which we have yet become acquainted; and although it is essentially a human histology, points of comparative interest have been, for the most part, duly noticed.

The first nine chapters are from the pen of the editor, Dr. Satterthwaite. He first disposes of the technical portion of histology, explaining what apparatus is necessary for work, and how it is to be used. Histological methods of examination are fully discussed, and yet not so fully as to confuse the beginner by an *embarras de richesse*. The blood, epithelium, and tissues forming the connective-substance group are then very thoroughly described in five separate chapters. Following these is a good description of the teeth, and quite a lengthy chapter on the general histology of the nervous system. In the contributions of the editor, which are marked throughout by practical good sense and precision of style, we find, among other points of general interest, some original observations on the structure and development of tissues belonging to the connective-substance group.

Muscular fibre forms the subject of the tenth chapter, which is by Dr. Dwight. Here also we find the presentation of the results of some original observations on the intimate structure of a highly interesting kind of tissue.

Dr. Wendt is the author of the next chapter, which discusses the blood-vessels. He expresses his belief in the physiological occurrence of endothelial desquamation; and he is inclined to regard certain corpuscular elements of the blood hitherto known and described as microcytes, hæmatoblasts, etc., as evidence of the normal occurrence of such desquamation.

In the chapter on the lymphatic system, Dr. Birdsall has prepared a very satisfactory *résumé* of our present knowledge concerning a very important subject, standing as it does in intimate relationship with physiology and pathology.

The chapters on the liver and kidney, by Dr. Mayer, might have been improved by less attention to technical details, and a more complete discussion of current views. The author has, however, made a very careful and elaborate study of the minute anatomy of these organs, and, among other things, he makes a very positive assertion in regard to the bile-capillaries, he being convinced that these minute channels are provided with walls of their own.

The male and female genital organs are considered by Dr. Simes. His chapters contain a simple presentation of the histology of those parts, without any attempt to settle disputed points by evidence based on personal studies.

Of the chapter on the respiratory tract, by Dr. Westbrook, it may be said that it explains clearly the microscopical structure of the different organs subservient to the breathing function.

An elaborate chapter is that on the skin, by Dr. Robinson. Decided opinions, some of them at variance with current views, are boldly formulated by the author. As they indicate his perfect familiarity with the subject, they deserve to be carefully read by the student and practitioner. His chapter also contains original observations on certain peculiarities of cutaneous nerve-termini.

Dr. Amidon's chapter on the central nervous system lacks somewhat in clearness, fulness, and systematic arrangement. There is too much description of the appearance of consecutive microscopical sections, and too little grouping together of co-ordinate points. But perhaps the intricacies of cerebral and spinal histology hardly justify the presentation of this subject to the student otherwise than by the description of successive and characteristic sections.

The chapter on the eye, by Dr. Williams, that on the ear, by Drs. Whitney and Blake, those on the nasal fossæ, pharynx, and tonsils, the mouth and tongue, by Dr Delavan, as well as that on the alimentary canal, by Dr. Wendt, contain very satisfactory presentations of the histology of these respective parts.

A chapter, by Dr. Dana, on the spleen, the pancreas, the thymus, thyroid, and pineal glands, and the pituitary body, conveys in a lucid manner all the necessary histological information on these various glandular bodies. The thick cutis vera is described in a separate chapter. Dr. Warren therein sets forth his discovery of an integral portion of the skin (*i.e.*, the fat-columns), which, according to him, play an important role in certain hitherto imperfectly understood cutaneous changes.

The remaining chapters are on the urinary excretory passages and suprarenal capsules, by Dr. Wendt, and the mammary gland, by Drs. Porter and Wendt.

The last chapter, that on the mamma, is one of the best in the book, and we are pleased to find in it an adequate recognition of Creighton's remarkable views on the female breast. Some interesting points relating to the ultimate morphological changes concerned in the secretion of milk are developed, the authors holding that mammary epithelium is not necessarily destroyed in their physiological process.

The illustrations are for the most part the familiar ones found in the text-books of Frey and Stricker. But we also discover sixty-five original drawings, the majority of which are very well executed. The bibliographical indices have been wisely made to include only the more important references, especially those of recent date. In taking leave of this volume, we have no hesitation in recommending it as the best and most serviceable work of its kind in the English language. It will be a reliable and most useful guide to students, and a practical work of reference to practitioners. We have no doubt that, as soon as known, it will be speedily adopted by our colleges as the standard American text-book on histology.

THE COMPEND OF ANATOMY FOR USE IN THE DISSECTING-ROOM. By JOHN B. ROBERTS, A.M., M.D. Second edition, revised. 18mo, pp. 193. Philadelphia: C. C. Roberts & Co. 1881.

THIS useful and practical compend appears in a surprisingly short time in the dress of a second edition, previously revised. It is designed for use in the dissecting-room and in preparing for examination.

ON THE ANTAGONISM BETWEEN MEDICINES, AND BETWEEN REMEDIES AND DISEASES, BEING THE CARTWRIGHT LECTURES FOR THE YEAR 1880. By ROBERTS BARTHOLOW, M.A., M.D., LL.D. 8vo, pp. 122. New York: D. Appleton & Co. 1881.

WE doubt if the true value of these lectures by Dr. Bartholow has been appreciated by the profession as they should be. They form, next to Wood's work, the best contribution to physiological therapeutics which has appeared in the English language. It is not that so much original research is displayed, but the author has summarized the latest facts regarding the physiological action of drugs in a masterly manner, and has presented them in such a way that no one can read his book carefully without being profoundly impressed with the method of studying therapeutics therein advocated. It is as a plea for the scientific study of the actions of remedies that these lectures have their highest value. Empiricists may still scout at the results to therapeutics of physiological experiment. But they cannot deny the accomplishment of some good already, nor can they point any other path that can lead us out of the present uncertainties of medical practice. Dr. Bartholow shows some natural over-confidence in his methods and dogmatism in his statements. It is not to be forgotten that empirical and experimental study must go hand in hand. But we welcome, and urge attention to, a work which, like the one before us, shows so ably the things accomplished and possible in physiological therapeutics.

BOVINE TUBERCULOSIS IN MAN: AN ACCOUNT OF THE PATHOLOGY IN SUSPECTED CASES. By CHARLES CREIGHTON, M.D., Demonstrator of Anatomy in the University of Cambridge. With illustrations. 8vo, pp. 119. London: Macmillan & Co. 1881.

THE object of Dr. Creighton's essay is to show the pathological identity of certain cases of tuberculosis as they occur in man, and the bovine variety of this disease. In view of the fact that we are often

brought in close contact with the bovine species, the question of the transmissibility of "Perlsucht" becomes one of great practical importance. The author stands on purely morphological ground. If we grant that identity of form and structure prove an identity in the specific nature of an affection, then we must except his views that bovine tuberculosis may be, and actually is, communicated to man. Creighton adduces carefully prepared evidence to show that the disease in man is, morphologically at least, a perfect mimicry of the parent disease in the bovine animal. He rejects totally the doctrine of Klebs and his followers, who believe in the existence of specific micro-organisms as the cause of infection. But he leaves the vexed question as to the exact and ultimate manner of infection in much the same unsettled condition in which he found it.

The great value of scientific works of the kind offered in the pages of the author's book consists not in the final settlement of disputed or imperfectly understood points, but in stimulating further inquiries by presenting matters in a new light. The pathological research of our times is gradually drifting away from man as an isolated being, and concentrating its attention upon subjects of general biological significance. There is much of promise in this modern tendency to establish a science of comparative pathology, and all efforts in that direction should be encouraged by the profession. On the whole, Creighton's arguments and opinions are suggestive rather than conclusive, but in any case they are deserving of attentive study. The drawings and plates are excellent, and leave nothing to be desired.

THE SANITARY CARE AND TREATMENT OF CHILDREN AND THEIR DISEASES: Being a Series of Five Essays. By Drs. ELIZABETH GARRETT-ANDERSON, SAMUEL C. BUSEY, A. JACOBI, J. FORSYTH MEIGS, and J. LEWIS SMITH. Prepared by request of the Trustees of the Thomas Wilson Sanitarium of Baltimore, Md. Boston: Houghton, Mifflin & Company. The Riverside Press, Cambridge. 1881.

BY the will of the late Thomas Wilson, Esq., of Baltimore, there was left the sum of five hundred thousand dollars in the hands of trustees, for the purpose of providing a sanitarium for children, near that city. The trustees, in a letter issued in 1879, expressed "the desire to furnish themselves with the results of the experience and views of those whose attention and studies have been devoted to the sanitary care and treatment of children and their diseases," also "the best method of establishing a sanitarium for sick children." This volume contains such suggestion embodied in the essays: "How can Children in a City be kept Healthy?" by Elizabeth Garrett-Anderson, M.D., of London, England; "The Mortality of Young Children—Its Cause and Prevention," by Samuel C. Busey, M.D., Washington, D. C.; "On the Improvement of the Condition of Poor and Sick Children—General Principles, etc.," by A. Jacobi, New York; "Observations upon the Sanitary Care and Treatment of Children and their Diseases," by J. Forsyth Meigs, M.D., of Philadelphia; and "Causes of the Great Mortality of Young Children in Cities during the Summer Season, and the Hygienic Measures required for Prevention," by J. Lewis Smith, M.D., of New York. There is also a plan of a sanitarium designed by Dr. Smith and carried out by Mr. J. B. Robinson, architect, of this city. The different essays show the result of careful study and reflect much credit on the writers. A better knowledge of the methods of establishing sanitariums for children, and their management, is greatly needed. Such institutions are being provided in the vicinity of many of our large cities, but we fear that the usefulness of many of them is sadly crippled by faulty construction and imperfect methods of management. There is therefore a demand for a book of this character, which not only points out the danger to which infants of the lower classes are exposed during the hot weather in our cities, but gives directions by which, to a certain extent, the danger to their health may be successfully warded off. It is a book not only for sanitarians, but one that may be read with great profit by all who have to do with the care and bringing-up of young children. There is little to criticise and much to commend in these essays: any extended remarks on them would simply be an analysis which our space does not permit. We therefore can only cordially recommend the volume to the profession and the public. The very attractive manner in which the publishers have done their work deserves special mention.

# Reports of Societies.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, September* 28, 1881.

DR. T. E. SATTERTHWAITE, PRESIDENT, IN THE CHAIR.

DR. WILLIAM H. PORTER presented, on behalf of a candidate, a

DOUBLE ANEURISM OF THE PULMONARY ARTERY.

DR. B. A. WATSON presented a specimen of

LACERATION OF THE LOWER LOBE OF THE RIGHT LUNG CAUSED BY VIOLENCE, WITHOUT FRACTURE OF RIBS, TERMINATING IN DEATH.

It was accompanied by the following history: Mrs. C——, a strong and healthy woman, aged thirty-three years, gave birth to a child one month before her death; five days after her confinement she was out of bed and attending to her household duties, which she continued to do uninterruptedly until about 6 P.M. September 7th, when she was kicked out of a chair by her husband, and then three or four times while lying on the floor. During the morning of September 8th she was seen to leave the bed for a few minutes, and lean on the furniture of the room for support. She again arose about noon and prepared dinner for her husband and children, but returned immediately to her couch, on which she was found dead at 4 P.M. of the same day.

*Post-mortem appearances.*—The autopsy was made about twenty-four hours after death, and disclosed the following conditions: Body well nourished; slight *rigor mortis;* blood oozing from mouth and nostrils; a triangular-shaped contuso-lacerated wound over the centre of the right scapula, two and one-half inches in length by three and one-half inches in breadth; the skin over this space was abraded and rolled on itself, and the tissues beneath contused and infiltrated with blood; there was also observed on one of the lower extremities a discoloration of a considerable portion of integu-

ment, which was evidently due to a bruise, but believed to be without pathological significance.

The examination of the head showed the scalp, cranial bones, investing membranes, and the brain substance, in a normal condition.

*Examination of the thorax.*—It was observed where the sternum was raised, that the lungs appeared to fill the whole thoracic cavity, and did not contract as usual on the admission of air. There were no pleuritic adhesions. The right lung having been carefully raised from the cavity, the lower lobe was found to be irregularly congested, and to present a contused appearance; its substance at various points was partly disorganized and much infiltrated with blood, and on its posterior surface was discovered a laceration measuring two and one-half inches in length. The right pleural cavity contained about two pints of fluid blood. The *ribs were not injured*, but on the interior of the right thoracic wall were discovered three or four ecchymotic spots, and on further dissection these were found to be continuous with the same number of ecchymoses, which involved the soft tissues in the intercostal space between the seventh and eighth ribs. There were observed on the surface of the left lung four or five dark-colored spots which, being laid open, were found to be much infiltrated with blood. The trachea and bronchi were found to contain some fluid blood, and there remained adhering to the mucous membrane a few coagula. The heart and its appendages were apparently healthy.

*Abdominal examination.*—Spleen and kidneys normal; liver slightly fatty, but not to such an extent as to be inconsistent with health, while the uterus was found in a state of subinvolution and with what appeared to be a portion of a placenta adhering to the inner wall of its fundus. All the other organs in this cavity were apparently healthy; but the blood here, as everywhere else in the body, was remarkably free from clots, and almost entirely fluid.

*Remarks.*—The general professional interest which attaches to this case, arises from the laceration of a healthy lung by violence without a fracture of the ribs, but there are also many important medico legal questions which are sure to arise in connection with any judicial investigation.

Dr. Watson also presented a specimen of

SUBINVOLUTION OF THE UTERUS: PORTION OF PLACENTA ADHERING TO THE INNER WALL OF ITS FUNDUS.

This specimen was removed about twenty-four hours after death from the body of a strong and healthy woman—multipara—whose death had been caused by violence about one month after confinement at full term. The uterus was in a state of subinvolution, and contained, still adhering to the inner wall of its fundus, what appeared to the unaided eye to be a portion of placenta. It was thought the specimen might possess some interest to the profession on account of its comparative rarity; but it possessed for him a still greater interest, arising from the retained placenta-portion, in connection with the almost complete absence of coagulability in the blood observed in every part of the body during the post-mortem examination. Was not this patient suffering at the time of her death from a mild form of septicæmia; and did not the diminished coagulability of the blood depend on this morbid condition?

The specimens were referred to the Committee on Microscopy.

Dr. Ripley asked if the presence of such an amount of placenta in the uterus at that period after confinement was abnormal.

Dr. H. J. Garrigues said that he should answer the question decidedly in the affirmative. There should be simply an uneven surface, showing where the placenta had been attached, and not a mass which had a well-defined thickness, as seen in the specimen. Evidently a portion of the placenta had been torn off, and remained attached to the fundus of the uterus.

Dr. Ripley said that he had on several occasions, at about the same period after confinement, seen such patches within the uterus, and no abnormal symptoms whatever had been developed. That was why he asked the question.

The President remarked that he had in several specimens found a simple roughness at the placental site between the second and the fourth weeks, but had not seen such a mass left behind as was present in Dr. Watson's specimen.

Dr. Ripley remarked that it was not uncommon for the placenta to remain after labor, and finally require the introduction of the hand to tear it off and remove it. In such cases, more or less of the placenta was usually left. Now, in certain cases of apparently normal labor, a certain amount of placenta might be left, and he was quite sure that several times he had seen as large a mass as that in Dr. Watson's specimen a number of weeks after labor. That it was abnormal he did not dispute, and that it was not uncommon he believed.

Dr. Garrigues remarked that probably portions of placenta might be left when the hand was introduced into the uterus for its removal, but he thought the woman under such circumstances was always in more or less danger from hemorrhage, septicæmia, etc. Such pieces might remain without giving rise to symptoms, but, as a rule, when it was found that they had remained, they should be removed at once.

The President asked if the remaining portion of the placenta was undergoing decomposition at the time of death.

Dr. Watson replied that decomposition evidently was taking place, though not rapid, and there was an offensive discharge during life.

Dr. J. Lewis Smith thought that blood-poisoning was more to be feared than hemorrhage, and that was the more prominent reason why all portions of the placenta should be promptly removed.

Dr. Ripley remarked that the placenta is frequently retained after abortion without giving rise to septicæmia.

Dr. Carpenter suggested that the specimen illustrated retention of a portion of the placenta after labor at full term.

Dr. H. J. Garrigues presented a specimen of

ABORTIVE OVUM,

with the following history: A patient, who had been married three years, and was the mother of one child, two years old, came to him on the 6th of last August, wishing to know whether or not she was pregnant. She said that menstruation had been regular up to last January, but that since that time she had not had her courses. Four months afterward (in April) she was examined by a competent man, who told her that she was pregment. After that she was treated for catarrh of the uterus, and she had herself noticed that her abdomen did not increase in size.

On examination, the first thing Dr. Garrigues no-

ticed was a dark, greenish-colored mucus coming from the vagina, and after the speculum was introduced, he satisfied himself that this material came from the uterus. Microscopical examination of the discharge did not reveal any anatomical formation. The uterus was no larger than it is usually in cases of so-called chronic metritis; and especially there was no marked enlargement in the antero-posterior diameter, a most important point as bearing upon the question of the existence of pregnancy.

Dr. Garrigues, therefore, told his patient that she might be two or three months advanced in pregnancy, probably not more than that, if at all, but that he would not introduce a sound into the womb to determine positively. He did not think that she was seven months pregnant, as indicated by the cessation of menstruation. He was willing to treat the cervix, did so, repeated the application at the end of three days, and on the evening of the fourth day the patient was taken with violent pain in the loins and hypogastric region, and when he examined her he found the os open sufficient to admit the finger easily, and a round body was presenting through it. About one hour afterward the husband brought to him the specimen presented, which was, when he received it, a closed sac, with the exception of small holes that would admit a fine sound. The openings were so small that it would have been impossible for a body of scarcely any size to escape from within the sac. The outside of the mass, about the size of a goose-egg, but flattened, was rough, and, when it was cut open, the inside was found to be uniformly covered with a perfectly smooth membrane, which under the microscope proved to be structureless: that is, it had no epithelium. The specimen, however, had been in alcohol over night when examined, and it was possible that the epithelium had thus been destroyed, but more likely it was removed in another manner. The entire inner surface of the uterus was studded with cysts of various sizes, from that of a small pea to that of a hickory-nut. Some of these cysts were empty, while others contained a substance that corresponded with the greenish black material seen exuding from the mouth of the uterus. It was doubtless disorganized blood. The cysts were composed of a thin membrane, about one-sixth of an inch thick, made up simply of coagulated fibrin, and they were filled with coagulated blood. There was no trace whatever of a fœtus. The membrane which covered the entire inner surface of the uterus was the amnion. What had become of the chonori and the decidua he did not know. There was only a very moderate loss of blood at the time the mass was expelled, and the patient made a good recovery. Hemorrhages which destroy the ovum may take place in different situations. They can occur in the decidua, or between the decidua and chonori, or between the chonori and amnion, or finally they find their way into the interior of the ovum.

The society then went into executive session.

---

Another Confidence Doctor.—We were recently called upon by a man who represented himself as a physician from St. Louis in straitened circumstances, who wished to obtain funds on a bogus draft. If he is no more successful with others than with us, he may soon choose other methods of living by his wits. In the meantime it may be well for our readers to look out for him.

## MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

*Stated Meeting, September* 26, 1881.

Dr. F. A. Castle, Vice-President, in the Chair.

Dr. W. Gill Wylie read a paper on

THE ETIOLOGY, PATHOLOGY, AND PREVENTION OF LACERATION OF THE CERVIX UTERI.

Under the head of etiology, the author referred to labor as the most common immediate cause. He then spoke of predisposing causes, such as intermarriage among different races, and a consequent ill-balanced relation between the size of the child's head and the cervix of the mother; abnormal conditions of the cervix itself, as imperfect or abnormal development, induration or loss of substance, and diseases of the mucous membrane. In cases in which the mucous membrane of the cervix continued diseased throughout pregnancy, laceration was very sure to occur during labor; and, even though it be slight, it might be very troublesome.

When a woman with a small and hard, or long and bent cervix, became pregnant, the cervix would soften in a great measure before labor, but it did not always become soft and perfectly normal. Even if it did soften, the cervix would be relatively feeble and small.

The immediate causes which tend to rupture the cervix during labor, even though the condition of the cervix be normal, were abortion, precipitate labor, labor in which delivery takes place soon after it begins, early rupture of the membrane, dry labor, retarded or protracted labor, instrumental labor, abnormal presentation, abnormally large fœtus or head.

After directing attention to certain points concerning diagnosis, Dr. Wylie spoke of the pathology of the lesion, and discussed the question: Why is it that lacerations are so commonly found through the lateral, and are comparatively rare through the anterior and posterior walls? The reasons given were: 1, the longest diameter of the pelvis at the brim is transverse, and therefore the longest diameter of the head is directed transversely; 2, the position and attachment of the uterine ligaments favor lateral laceration; 3, the rectum and bladder pad the anterior and posterior walls of the cervix when fully dilated; 4, the muscular structure of the cervix favors its anterior and posterior walls.

The tissues of the cervix were then studied, and the relation which they bear to the changes that occur after laceration has taken place. The causes enumerated of eversion of the tissues when the cervix had been lacerated were: 1, the condition of the cervix at the time it was torn; 2, increase in size of the soft and vascular mucous membrane and connective tissue in or near the laceration; 3, swelling or thickening in the adjacent connective tissue involving the ligaments of the uterus; 4, the upright position; and 5, pressure, under certain conditions, upon the posterior wall of the vagina and underlying parts of the floor of the pelvis.

Dr. Wylie did not accept Dr. Emmet's theory that it was the cicatricial plug which causes a hyperæsthetic condition in the womb, which, by reflex action, greatly disturbed the health of the patient in some cases. He thought the condition was similar to what was found in other portions of mucous membrane where there was no cicatricial plug; for example, sensitive spots in the vaginal cervix, in the

female urethra and vagina, in the prostatic portion of the male urethra—points which were equally sensitive and produced very similar reflex disturbances.

With regard to prevention of laceration of the cervix, Dr. Wylie believed that much might be done by treatment previous to and close attention during labor, and also that the accident could be limited and its serious effects be restricted. He regarded morning sickness as a quite certain indication that the neck of the uterus was in an unhealthy condition. Leucorrhœa during pregnancy should be treated He believed that, with reasonable care, many more cases of abortion and premature labor could be obviated that were caused by improper local treatment. Application could be made to the cervical canal to the distance of three-fourths of an inch, and tepid vaginal injections could be used with safety during pregnancy. For the relief of morning sickness he had found dilatation of the cervical canal for three-fourths of an inch perfectly successful, not only in relieving the symptom, but in softening the hardened condition of the cervix so commonly associated with it. He thought if obstetricians would take as much pains to prevent laceration of the cervix as they did to prevent laceration of the perineum, much would be done to avoid the occurrence of this accident. The membranes should not be ruptured until absolutely necessary. The dilatation of a rigid os should be carefully and slowly assisted by means of dilators. Violent voluntary expulsive efforts at the time the head is passing through the cervix should be controlled, if necessary, by anæsthetics, and an effort should be made to regulate the expulsive force with the fingers against the head. The timely and skilful use of forceps in retarded labor often prevented sloughing and some of the more serious forms of laceration of the cervix. When used, the cervix should be dilated as much as could be done safely before the instruments were applied.

Dr. W. M. Chamberlain regarded Dr. Wylie's paper as one containing the results of careful observations accurately stated, and it was also full of suggestions, some of which were rather novel and interesting. The idea of hybridity as a predisposing cause of laceration of the cervix he regarded as novel, and yet he could easily see the philosophy of it. Dr. Wylie had indicated many of the points at which abnormal resistance might exist within the pelvis, and, while doing so, Dr. Chamberlain had thought particularly of that condition of imperfect development known as hypertrophy of the supravaginal cervix, accompanied with a conical os presenting anteriorly to the pubic arch. That was not an uncommon deformity, and, as a rule, it was encountered in sterile women, because the expansion and elevation of the uterus during gestation so far modified this condition as to render it less easily recognized. It had been accounted a frequent cause of sterility, and undoubtedly was such; still such women did become pregnant, and then the faulty development affecting the connective tissue, which makes the pubic arch the point of support in the main, for the uterus—namely, the intimate relation of the uterus with the bladder and with the coccygeal and obturator fascia and muscle, became the occasion of disturbed mechanical conditions. That is, if those tissues had become condensed and infiltrated as the result of disease, the uterus was stinted in its growth in front, and being so stinted, it developed along its posterior wall and produced the deformity, just as pleuritic adhesions formed in childhood do sometimes give rise to the curvature of the spine which shows itself as the frame develops after puberty. He believed that that condition predisposed to the occurrence of laceration of the cervix; for it not only confined the uterus to the pubic arch and rendered the anterior lip comparatively immobile, but, by a pouching of the posterior wall of the uterus, it permitted a disproportion of force to be applied to the posterior lip.

With regard to the action of the suspensory ligaments being the main cause of eversion of the lips of the lacerated cervix, Dr. Chamberlain thought that Dr. Wylie's view in that respect was somewhat novel. Dr. Sims had pointed out that when the circular fibres of the cervix were torn the natura antagonism to the action of the longitudinal fibres was destroyed, and therefore the latter retracted the lips of the torn cervix, and gave rise to the eversion.

Dr. Emmet had made more prominent what would seem to be a mechanical cause, in calling attention to the fact that the lips of the lacerated cervix were brought in contact with the walls of the collapsed vagina, and that the eversion was produced by friction.

Dr. Chamberlain suggested another cause for the eversion, which, to distinguish it from the physiological and the mechanical, he called *vital*; that is, he believed the cause of the eversion, in many cases, was nutritive, and he based his conclusion upon the following observations:

As often as he had seen laceration of the cervix, not quite transversely, but with one or the other angle turning upward, sometimes both, sometimes both turned downward, it had been a constant observation that the eversion was the greatest in the narrowest segment, and it was in the narrowest segment also that he had noticed the greatest amount of cystic degeneration and increase of connective tissue, sclerotic, semi-cartilaginous, causing and constituting the eversion. Moreover, when, as is generally the case, the prolonged use of the glycerine tampon is followed by absorption of this hard tissue, and puncture, followed by iodine, destroys the cysts, the eversion diminishes, though all other conditions remain the same.

With regard to the means to be employed for preventing laceration of the cervix, Dr. Wylie's recital would receive general assent. There might be, perhaps, some hesitation with reference to dilatation of the cervix, as indicated by morning sickness. He was not prepared to say that in every case of ordinary morning sickness dilatation of the cervix should be resorted to, but he was prepared to say, however, that the most aggravated cases of puerperal nausea had yielded to that treatment. He had employed the means, and would not hesitate to adopt it as a *dernier ressort* when medicinal treatment had failed.

Dr. H. J. Garrigues had listened with great pleasure to the elaborate paper, and there were only a few points upon which he entertained opinions at variance with those given by the author. With reference to the occurrence of the accident more frequently in this country than in foreign countries, and intermarriage of races as a predisposing cause, he doubted the correctness of Dr. Wylie's views, and believed that the great reason why it occurred apparently more frequently here than elsewhere was that the lesion was pointed out first by an American surgeon, who also gave a method of treatment, and the condition had not been recognized abroad as generally as in this country. In those parts of the world where Dr. Emmet's views had been recognized and his treatment adopted, ample material had been obtained for the operation. For Denmark he

could give some details, and in the city of Copenhagen, containing about two hundred and fifty thousand inhabitants, Dr. Emmet's operation had been performed sixty times by one surgeon.

With regard to the location of the laceration, Dr. Garrigues had not seen, nor did he recollect ever having seen a representation of a tear in the median line in the anterior or posterior lip without other lacerations. Of course, by far the most common form was that upon the left side, a little anterior to the centre, and next the stellate variety.

Among the causes, Dr. Wylie had mentioned the action of the utero-sacral ligaments as preventing laceration antero-posteriorly, but he doubted the correctness of that view. Dr. Garrigues thought that those ligaments were inserted too high up to have that power, for they passed off from a point corresponding to the internal os, and he thought that a laceration did not extend so high as that. With reference to prevention of the accident, he thought Dr. Wylie's remedies were very apt, and he could corroborate the results obtained, with the exception of those following dilatation, which he had not employed. He had used moderately astringent injections, vaginal and cervical, and had made local applications of the tincture of iodine, carbolic acid, etc., without provoking abortion and with apparent benefit to the patient.

Dr. Paul F. Mundé had not been able, for himself, to determine exactly what the cause of laceration of the cervix was, except in those cases, perhaps, in which it was manifestly due to mechanical injury. Dr. Bennet, of London, had expressed the opinion that the real cause existed in inflammatory infiltration of the cervix, but Dr. Mundé thought that the claim could not be maintained. Perhaps that condition existed to a certain extent, but he thought that it did not occur very frequently, and, besides, he did not believe that it could be proved that it was present. He had been unable to determine how to prevent the occurrence of laceration, simply because he did not know where it was to occur. Any means which would prevent too rapid labor, too rapid passage of the child's head through the cervix, doubtless would lessen the frequency of the occurrence of laceration.

Dr. Sell remarked that he had seen several antero-posterior lacerations, anterior as well as posterior, also bilateral posterior and bilateral anterior. He also referred to treatment without surgical procedure.

Dr. Putnam-Jacobi thought that Dr. Wylie's data were theoretical rather than those obtained from cases studied during the anterior history of the patient and compared with what occurred during labor. It seemed to her very certain that the accident could not be attributed to any general condition, as insufficient nutrition or imperfect development of the uterus, inferred from a more perfect or higher mental development of the patient.

It might be possible, however, to bring out some elementary conditions, and one of those which had been most frequently referred to was œdema of the cervix. When laceration was first pointed out, great stress was laid upon œdema as a cause, and consequently the timely application of the forceps has justly been considered as a means of prevention as frequently as an agent for causing the injury. To the same elementary condition, œdema, could be referred those cases of Dr. Bennet, of London, in which chronic catarrh had preceded labor where labor occurred; but the question of œdema could be thoroughly understood after analyzing it still further and estimating its effect upon the contractility of the smooth muscular fibre. Ranvier, in his recent researches upon the contractility of smooth muscular fibres, had pointed out this peculiarity, that the smooth muscle contracts in its sheath, that there is no independent contraction of fibres as in the striped muscle, and it was conceivable that the enfeeblement by liquid of the unstriped cells which make up the sheath would interfere with the propagation of the contractile wave, and in that manner interfere with contraction. It was quite probable that œdema existing in consequence of cervical catarrh was the efficient cause of the flexion which succeeded the catarrh.

Dr. Putnam-Jacobi pointed out further, that in a normal labor the lower segment of the uterus should have finished its contraction and become reduced in its condition of elasticity before the upper segment began to drive the head of the child through; consequently, in the most typical and efficient form of labor, there was nothing to prevent the head from being pushed through, because the lower segment of the uterus is in a non-resisting condition; but if, on the contrary, the upper segment contracted too violently, the head was driven against the lower segment and an injurious degree of pressure exerted before the elasticity of that segment has been sufficiently reduced to avert the effect of it.

Dr. Wylie, in concluding the discusssion, said that he had seen antero-posterior laceration at the Woman's Hospital, although he had not met with that form in his own cases.

With regard to the utero-sacral ligaments, he did not think that they acted in all cases as a cause of laceration, but when the head carried the cervix very low down, then the tendency to pull the cervix back might be an efficient cause of laceration; but only in certain cases.

With regard to the attachment of the ligaments, he thought that they were more or less attached to the lower portion of the cervix, and, therefore, might be more or less efficient factors in the causation of laceration. With regard to inflammation being a cause of laceration, he was satisfied that he had seen three cases, at least, in which it was. His view was that by the inflammation the tissues of the cervix were weakened, and when in labor the cervix was placed upon the stretch, the least tear would extend much farther than if the tissues were in a perfectly healthy condition.

With reference to the data upon which his paper was based, they were such as he had obtained by the study of cases before and during pregnancy, and during and subsequent to labor.

On motion by Dr. Piffard, the thanks of the society were extended to Dr. Wylie for his interesting paper.

The society then adjourned.

---

International Medical Congress.—We understand that the proceedings of most of the sections of the late International Medical Congress will shortly be published and sold in a separate form. In view of the ultimate distribution by mail of the complete proceedings, the members of the International Medical Congress in the United States, residing in large cities, who neglected to give their full address when registering, should send the same at once to Dr. William McCormack, 14 Harley street, London, Eng.

# Correspondence.

## IS GUITEAU INSANE?

To the Editor of the Medical Record.

Sir: The writer of the very objective and fair editorial in The Medical Record of October 22d, does not seem to have had at his disposal the following facts, which, if duly weighed, would, I believe, render him more positive in assigning Guiteau to the class of the unquestionably insane. 1st. Guiteau entertained the delusion that if he obtained a certain position in a foreign embassy, a wealthy woman would marry him and endow him with a million dollars, wherewith to maintain his social position. This idea either was a delusion without any basis whatever, or with so frail a basis as to warrant the formation of such a day-dream to no sound mind; at all events, it was an insane conception. 2d. The letter found in his pocket after the assassination, ordering General Sherman to take possession of the jail, aside from its general tenor, which would immediately rouse the suspicions of any experienced alienist, can be interpreted in only one of two ways, either as an attempt to sham insanity on the part of the writer, or as an isolated but distinct proof of actual insanity. 3d. That Guiteau when arraigned for trial was checked in attempting to read a document, which, however, found its way into the columns of the New York *Herald*, and is an even more characteristically insane document than the letter to General Sherman. 4th. That as far as an almost unanimous testimony of lay witnesses and existing pictures of the assassin permit us to judge, Guiteau has the characteristic "insane manner" in a high degree, as well as a suspicious cranial configuration. 5th. That six months before the assassination, Guiteau applied, if I recollect rightly, for a pension, and the examining surgeon made this brief but today weighty marginal note to the application, now on file: *Applicant is insane!* 6th. That Guiteau used to have a placard in his room reading "Guiteau, Premier of England," and on different occasions gave other evidences of entertaining the ambitious delusions of what the French term *megalomanie*, and which Marcé more happily designated as *folie systematisée*. To be brief, I would say that the just pride of American psychiatry, Isaac Ray, would today turn around in his grave if he had heard the latter-day members of the association, whose conservative policy he was the ablest defender of, declaring Guiteau sane, in newspaper interviews, held after the assassin's hereditary relations, his documents, and other details had become known. When Mr. Blaine, Senator Logan, nay, the deceased victim of the assassin, and an impartial physician had recognized the insanity of Guiteau, and some of those who are supposed to devote their lives to the care and study of the insane unhesitatingly pronounce him sane, the value of the "asylum experience" argument becomes finely illustrated.

The claim made in several journals that Guiteau is legally responsible, because "he knew what he was about," now shows a fear of death, took measures to secure himself against mob violence, etc., sounds rather like the prevailing cant among a certain class of lawyers than the deliberate opinion of scientists. No competent alienist ever attached weight to the apparently and at times actually methodical actions of lunatics, except to consider those very lunatics more dangerous than their weaker-minded comrades, and therefore believed it incumbent to sequestrate such lunatics, before all others, for the safety of society. There is not a scintilla of doubt in my mind, that if Guiteau with his hereditary history, his insane manner, his insane documents and his insane actions were to be committed to any asylum in the land, he would be unhesitatingly admitted as a proper subject for sequestration. The conclusion concerning his legal responsibility following from this is so self-evident that it will require no rebuttal of the "mad dog" argument urged in interviews and even in acknowledged works of merit, on my part, to distinctly set it forth. If the ridiculous dictum were to prevail, that lunatics are to be held responsible for all acts whose nature they appear to understand, our experts might sink to the intellectual level of the jury that pronounced Gosling sane, because he seemed to be well posted on the trial, without any loss to the science of medical jurisprudence. Gosling, in some respects at least, would at that time have behaved less absurdly than Guiteau; within sixteen months thereafter he died of paralytic dementia in a private asylum near Philadelphia!

A thorough study will convince an impartial and competent jury of medical examiners, before whom such a case should be laid, that Guiteau is not only now insane, but that he was never anything else, that his crime was the offspring of insanity, and that in every act he will betray the characteristic features of querulent monomania. They will also conclude that, inasmuch as his insanity is not the result of his own vices, but based on a defective organization inherited from a diseased ancestry, anything like responsibility, complete or partial, is out of the question.

Not a day passes but adds another to the accumulating evidences in favor of the view here expressed. In a recent issue of the *Herald*, I find that the assassin has threatened President Arthur that unless he is allowed fees for witnesses, etc., he will publish documents that will ruin the Republican party. What but a complete confusion of the logical apparatus can account for such vaporings, evidently made in all seriousness?

It will be a matter of regret if the Guiteau matter ever comes before a jury. The temper of the whole land, and justly so, was never before so much excited against an individual as against this assassin. Sane or insane, the narrow-minded official conducting this trial, whom Judge Hoar has already censured for his intemperate zeal that has carried him on more than one occasion beyond the legal limits in this case, will find "experts" who will be only too willing to chime in with the public against what public prejudice stigmatizes as the "insanity dodge." And while the death by the gallows of a lunatic, and particularly of one presenting the repulsive though morbid features of Guiteau, may be no material loss to the land or his family, yet it is to be feared that his conviction, which, if he is, as I strongly believe, clearly insane, would be nothing but a formal lynch process, will reflect great discredit on American medical jurisprudence.

The one feature of which the profession may well be proud in connection with the Guiteau case, is that the insanity of the assassin was recognized by many of our journals, edited by practical physicians, while, in uncreditable contrast, an organ of asylum

officers expresses itself rather adversely to that idea, and several superintendents of asylums pronounced Guiteau sane to newspaper reporters.

Yours, etc., PHILALETHAS.

[Our correspondent presents his side of the case very strongly. There is not, however, enough of substantiated evidence to weaken materially the view we have taken.—ED.]

## VIRCHOW'S TRIBUTE TO AMERICAN MILITARY MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR—There was, by some mistake of mine, an omission in my "Address," published by you in the last number of the MEDICAL RECORD. Unless space forbid, after you have sacrificed so much of it in my favor, I ask you to print these additional lines. The last half of them, containing a quotation from Virchow, will prove a source of interest and gratification to the profession.

Very respectfully yours,
A. JACOBI, M.D.

The addition comes in after the line "like the best and noblest of us," near the bottom of the second column, p. 457, and reads as follows: as also, for the rank and file of the practitioners of medicine, he is the model of a professional brother and colleague. He is one of the most assiduous and regular members of the local medical societies, participating in scientific discussions, and serving the common interests of the profession. The same spirit of humanism and solidarity which presses him into the service of the city and country, makes him an active associate of the medical community. Too often do we meet the contrary. Those who have risen and advanced, partly through their own efforts, partly, however—and not very rarely—through the favor of their fellows, are too apt to forget that they are but branches of the same tree. In our own midst we notice too frequently, that those whose co-operation and example would make them the most desirable members, keep away from the societies of the county, State, and others. The individualism and egotism of the industrial period of the nineteenth century, so rife among the manufacturing and commercial classes, threatens to invade the medical profession to an undue extent. There is no man, however, who sacrifices more time, and does more work to foster professional feeling and brotherhood, than Virchow. Hardly any of the great scientific national and international associations and congresses takes place without Virchow being present. No question arises where universal knowledge and the weight of a great name are required, but his voice is heard. But lately, in London, he raised it in favor of protecting and saving the physiological experiment.

Both his universality and urbanity, as also his sense of justice, are of peculiar interest to us, the American profession. Many are the occasions on which he expressed his appreciation of the republican autonomy of the medical men in this country, of the efforts on the part of medical societies in behalf of the suppression of quackery, and also of the scientific results of American medical labor. Let me quote but one passage from an oration delivered on August 2d, 1874, "On the Progress of Military Medicine." Virchow says (page 6):

"The French army lost, in the Crimean war, thirty-three per cent. of its men, viz., 95,615. Of this number, 10,240 were killed on the battle-fields, and about as many died of their wounds in the hospitals. More than 75,000 men died of infectious diseases. In the American civil war 97,000 died of their wounds, and 184,000 perished of infectious and other diseases. What a vast amount of pain and misery! What an ocean of blood and tears! And besides, what a number of errors, mistakes, and prejudices! It is not necessary to now enumerate the long list of blunders and sins. They are so well known as to serve in the future as warning examples.

"Let me say here that it was not misfortune alone that showed where the cause of the evil was, and then provided aid. If the French learned little or nothing in the Crimea, and the Americans so much in their civil war as to create a new era in military medicine, the explanation is not to be sought for in the immensity of misfortune and misery undergone by the Americans, for they did not suffer any more than the French did in the Crimea. The explanation is in the critical and thoroughly scientific spirit, the clear perception, the sound and practical common sense which penetrated gradually every part of the American military administration, and which, with the astounding co-operation of an entire nation, accomplished more humane results than any great war ever produced before. Whoever studies the copious publications of the medical staff of the American army, must again and again be astonished at the vast experience collected in them. Absolute accuracy of details, the most painstaking statistics, acquaintance with all branches of medical learning, and a comprehensive style, are united in them for the purpose of collecting and preserving, in the interest of the present and future generations, the new knowledge so dearly bought."

So says Virchow.

## PIGEON-LICE INFESTING THE SKIN OF A WOMAN.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Some time last spring, a tall, gaunt, cachectic woman, with a yellowish skin, but pearly white sclerotics, came to my office, complaining of intense itching all over her body, avowing that her trouble was caused by insects crawling over her. I examined quite carefully, but I could find none. She maintained, nevertheless, that she had often seen them crawling out of her skin and crawling in again.

As a number of patients happened at the time to be waiting, I told her to go home, and when any more of the vermin began to crawl over her, to catch some of them, put them in a phial, and bring them to me.

In a few days she came again, this time bringing a phial containing a number of small insects, with which, unfortunately, I was not familiar.

Moreover, she said she came prepared to show me the insects crawling out of her skin, for she had found that, as soon as she began to sweat from any cause, they would crawl out of her skin and over it, and that, if I had the time to spare, she would show the going in of the same. I told her I was ready, and forthwith she put on some wraps which she had brought with her, and drinking a bottle of hot tea, drew near the fire, and soon began to sweat.

As soon as the skin began to moisten, small black or brownish insects emerged singly, in pairs, or in triplets, from numerous points. After the sweating ceased, the insects, as the woman asserted,

crowded into her skin again. *The points where they entered and emerged were the sweat-pores*, which made cosey nests for them at ordinary seasons, but were apparently not to their taste when deluged with sweat.

I sent the specimens which had been caught to my old friend, Dr. John Le Conte, of Philadelphia, whose inquiry into such questions is a sort of court of last resort. He answered that the insects were *pigeon- or hen-lice.*

When the woman came again, she stated, on inquiry, that she had no chickens about her house, but that there were some pigeons nesting in the garret, and that she sometimes handled them and cleaned their nesting-places.

The woman was finally directed to get rid of the pigeons, wash the nesting-places with tar-water and a solution of corrosive sublimate (twenty grains to the bucketful). As to those upon her person, she was advised to take sweats occasionally, and, when the lice began to scamper about, to rub over her person sulphur-powder, made into a sort of cream with tar-water, and to boil her clothes. She has not had further trouble with the lice.

During a recent visit to Philadelphia I called on Dr. Le Conte, and asked him to give me some information, if any he had, about these lice. He was good enough to have his secretary transcribe the following, which I take to be the sum and substance of what is known about the matter:

*Economic Entomology—Aptera*, by Andrew Murray, F.L.S., "South Kensington Handbook."—"No. 16. Dermanyssus Nitzschll (Giebel, in *Zeit. Ges. Naturw.*, iv., 29).—16, enlarged figure of ditto, copied from Giebel's figure.

"This is the species from the nostrils of the goat-sucker, of which we have above spoken. It feeds on the blood of its victims; it is as big as a head-louse, and as many as twelve to fifteen were found together in the nostril of the same bird.

"Nos. 17, 18, 19, 20, 21. Dermanyssus Avium (Dug.).—17, enlarged figure of ditto, empty; 18, specimens thereof; 19, vignette (realistick chick); 20, enlarged figure of ditto, fed; 21, specimens thereof. The so-called 'tick' infests domestic poultry, canaries, and other cage-birds. It lives especially in fowl-houses and on the inhabitants, and they sometimes migrate from the birds to the persons of those who have charge of them, and occasion them much annoyance. Alt (a German observer) saw these, or a mite which he supposed to be of the same species, upon the neck and arms of a cachectic old woman. According to him they were white, of the size of a grain of sand, extremely agile, and slipped out of little excavations (occupying the space of 1½ square line), ran over the skin, and back again into their holes.

"Simon narrates a case in which the mite nestled upon the skin of a woman, who was otherwise healthy. She was constantly infested with little louse-like animals, notwithstanding great cleanliness and many attempts at extirpation of the mites, which were recognized by Erichson as the Dermanyssus avium. It was found at last that the woman went several times daily into the cellar, over which the hen-roost lay. As often as this was the case, the fowls flew up into their roosting-place, and by this means the woman was sprinkled with mites. The removal of the hen-roost cured her of her supposed phthiriasis. (Kuchenmeister Manual: Parasites, vol. ii., p. 64.)

"It also infests dove-cots, although no doubt it is sometimes confounded there with the Argas reflexus, which is more especially assigned to pigeons.

"It may be most easily observed in the cages and aviaries of singing-birds, and they may harbor there, even although the most scrupulous cleanliness is exercised, especially if the perches used for the birds are made of hollow canes, and not solid wood; it is in these hollow canes that they most particularly harbor, and we may generally find them there at all seasons of the year. But it is very probable that, although it is in these recesses that we find them when we seek them during the day-time, they sally out during the night and settle on the sleeping birds, in order to suck their blood. That they do so is shown by their digestive organs being generally full of it in all individuals, both young and adult. It is this blood which gives to these animalcules their color, which is dark purplish or brown, when they are filled; when empty, they are colorless. In the same retreats are found a multitude of excessively fine exuviæ, or white cast-skins, attesting sufficiently numerous moulting. In this heap are seen also colorless eggs, ellipsoid, nearly equalling in length the fifth part of the adult animal, which is scarcely a third of a line at the most.

"These eggs are said to become larger in maturing, and to take gradually, like those of the spider, the form of the young one which is coming out. The young have only six feet; the body is much longer and more inflated than that of the individuals of the same size which have already their eight legs; these last are slenderer and more agile, and the posterior pair are much longer than the body, and continue pellucid and colorless as at first; but it is not long before they go and fill their stomachs, and the blood that they swallow makes them bright red at first, then dull, then brownish, in proportion as it becomes more altered and digested.

"Bory de St. Vincent (Ann. Sc. Nat. Ist., ser. xxxv.) relates that a woman, forty years old, who felt the most intolerable itching all over her body, had only to scratch herself to see minute mites come out of her skin; but none of them spread to, or propagated the disease to, her attendants. Gervais named this species Dermanyssus Boryi, in compliment to the narrator."

Hoping this narration may be of some interest to your readers,

I am, yours, etc.,

M. Goldsmith, M.D.

Rutland, Vt.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October* 16, 1881, *to October* 22, 1881.

Tremaine, W. S., Capt. and Asst. Surgeon. The extension of his leave of absence on surgeon's certificate of disability granted him in S. O. 112, May 16, 1881, from A. G. O., still further extended three months on surgeon's certificate of disability. S. O. 238, A. G. O., October 20, 1881.

Dickson, J. M., Capt. and Asst. Surgeon. Granted leave of absence for four months. S. O. 232, A. G. O., October 13, 1881.

Adair, G. W., Capt. and Asst. Surgeon. Upon relinquishing unexpired portion of his present leave of absence, relieved from duty in Department of the East, and to report in person to commanding general, Department of Dakota, for assignment to duty. S. O. 230, A. G. O., October 11, 1881.

KILBOURNE, H. S., Capt. and Asst. Surgeon, Fort Porter, New York. Granted leave of absence for one month with permission to apply for two months extension. S. O. 182, Department of the East, October 11, 1881.

GARDNER, E. F., Capt. and Asst. Surgeon. Granted leave of absence for four months, with permission to apply for an extension of two months. S. O. 238, C. S., A. G. O.

## Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — **Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending October 22, 1881.**

| Week Ending | Typhus Fever. | Typhoid Fever. | Scarlet Fever. | Cerebro-spinal Meningitis. | Measles. | Diphtheria. | Small-pox. | Yellow Fever. |

PHI EPSILON.—A fraternity of this name has recently been established at the College of Physicians and Surgeons, New York. Its object is to promote a spirit of friendship among the students.

DR. J. GASPARD RIBAND, Professor of Anatomy in the Montreal School of Medicine and Surgery, and an eminent practitioner, died in Montreal, Wednesday night, October 19th.

CONSULTING WITH HOMŒOPATHS.—Dr. J. B. Stair, of Spring Green, Wis., writes: "Without presuming to criticise so eminent a man as Dr. Bristowe, it seems to me that medical men of the orthodox school must always take exception to such opinions as he is reported as expressing concerning consultation with homœopathists. It appears to my humble understanding that since so radical a difference exists between the doctrines of a regular physician and of a homœopathist, that, following these doctrines, any union of opinion as to the treatment of a given case would be *of necessity impossible;* it would be the sheerest folly to enter into a consultation that could end in no other way than in total disagreement. As well consult with the representative of any other ism as with that of Hahnemannism. Regular medicine —I say it without egotism, for it is a fact—embraces the best, in fact all there is of scientific, rational treatment of disease. Homœopathy (I refer to vol. xii., "Encyclopædia Britannica") has no scientific foundation. Let homœopathy give up her narrow tenets, and treat disease upon broad scientific principles, then Dr. Bristowe's suggestions could be favorably considered.

THE LATE DR. EDWARD T. DALE, of Texarkana, Ark., died suddenly at Little Rock, Ark., September 19th, at 3 o'clock P.M.

Dr. Dale graduated at Long Island College Hospital, in the year 1873, and in the fall of that year began the practice of medicine at Fulton, Ark., being associated with Dr. R. B. Christian of that place. In the early part of the following year he moved to Texarkana, where by constant application he succeeded in building up a large and lucrative practice. His deep interest in all public affairs thoroughly identified him as a leading and most useful citizen. Dr. Dale was one of the organizers of the State Medical Society of Arkansas in 1875, was one of its first vice-presidents, and in 1879 was elected president, which position he filled most creditably both to himself and to the society. He was also a member of the American Medical Association.

Dying at about the age of forty, in the prime of life and in all the vigor of manhood, his death is to be sadly deplored by the profession, of which he was a prominent and useful member, by the community as a most valuable citizen, and by his widow and two orphans as a kind husband and loving father.

A FIRE ON WARD'S ISLAND.—A fire took place a short time ago in the two-story building forming the kitchen and laundry of the Homœopathic Hospital on Ward's Island. Before help could arrive the building was nearly consumed. Six hundred patients were safely removed from the adjacent hospital and then brought back again.

MICROCOCCUS UREÆ.—Dr. George M. Sternberg, Surgeon United States Army, writes: "In my paper, entitled 'An Instructive Experiment,' published in THE MEDICAL RECORD, of September 24th, the generic name of the micrococcus which produces the alkaline fermentation of urine (*Micrococcus ureæ*, Cohn), has in several places been improperly changed by the printer or proof-reader to read *micrococci ureæ*, a small m being used instead of a capital letter, and the generic name being put in the plural, which is evidently inadmissible. The specific name, *ureæ*, adopted by Cohn for this micrococcus, is in the genitive case, and not in the nominative plural, as has, perhaps, been supposed by whoever made the change referred to.

The following correction should also be made: On page 340, first column, sixth line, for *ru*dimentary read *se*dimentary.

THE THERAPEUTICAL USES OF ERGOT IN NERVOUS DISEASES.—The now widely extended use of ergot in various nervous disorders make the following clinical notes regarding the drug of considerable interest. They are furnished by Dr. J. G. Rogers, superintendent of the Indiana Hospital for the Insane:

In this connection I will note the fact again that it is not alone to the influence of ergot and the bromides on the blood-vessel calibre that the potent effects are due, but that they both peculiarly and not exactly similarly do possess a power to repress excessive nerve-life to a certain extent. The bromide and ergot combination is used in such cases as do not positively require chloral. In milder types of active mania, ergot alone has seemed to exert a decided curative influence, and a large number of such cases have been solely treated with this agent with satisfactory results.

The experience of the year presented in the clinical records, in which the history of every patient is regularly kept, as explained in my last report, fully endorses the efficacy of ergot as a means of controlling cerebral plethora, whether active or passive. Its action is prompt and can be maintained in the majority of cases indefinitely without detriment. Beyond its special effect on the vasomotor system, which is now generally recognized, there is every reason to believe that it exerts a peculiarly con-

trolling inflence over the molecular life of nervous tissue when that life has gone beyond the physiological mean of activity and has become erethetic, excessive, and self-destructive—what in another less mysterious tissue would be recognized as inflammatory. Practically it does control mental excitement whenever associated with congestion, whether the subject be anæmic and exhausted, or otherwise. In cases of acute mania it seems to be always more or less applicable, and in the acute exacerbations of chronic mania it is equally so. Having no direct hypnotic effect, however, in those cases when delirium has lasted for many days and nights without ceasing, and the patient must either sleep or die, as is often the case when admitted, it is necessary to assist its action with chloral hydrate. This latter agent of itself in full dose tends to produce a secondary passive fulness of the head, but this effect is obviated by the ergot.

Carrier-Pigeons as Doctors' Assistants. — We learn from reports in the papers that carrier-pigeons are being made very useful by co intry doctors in this State and Pennsylvania.

A physician, of Erie, Pa., is training homing pigeons for use in his practice. Some of his young birds, put upon the road to make records for distance, have made very good time, viz., fifty miles in ninety minutes, sixty-six miles in eighty-two minutes. Homing pigeons are largely used by country physicians both here and abroad. One doctor in Hamilton County, N. Y., uses them constantly in his practice, extending over nearly two townships, and considers them an almost invaluable aid. After visiting a patient he sends the necessary prescription to his dispensary by a pigeon; also any other advice or instruction the case or situation may demand. He frequently also leaves pigeons at places from which he wishes reports of progress to be despatched at specified times, or at certain crises. He says he is enabled to attend to a third more business at least through the time saved to him by the use of pigeons. In critical cases he is able to keep posted by hourly bulletins from the bedside between daylight and nightfall, and he can recall case after case where lives have been saved that must have been lost if he had been obliged to depend upon ordinary means of conveying information.

Slow Pulse.— Dr. J. A. Rice, of Bridgeport, Conn., gives the following account of personal observations on the rate of his heart-beat: "Lying down, 36; sitting, 38; standing, 41; after walking one mile, 43; after walking two miles, 46; after violent exercise, 52 per minute. Beat counted at the apex-beat to avoid error. The other members of my family have natural pulses. I first noticed my peculiarity eight years ago, since which time it has not changed. I have not been sick enough to know what effect a fever would have on it. I have no valvular lesion or other trouble with the organ, though it is at times a little irregular. My health is at all times excellent. I know of no cause for the slow rate. My age is under thirty."

Aphorisms in Doubtful Cases of Pregnancy.— Dr. Robert Battey, at the late meeting of the American Medical Association, enunciated the following rules as a guide to diagnosis in abdominal enlargements in females: 1, always consider a married woman pregnant, if living with her husband, until *proved* otherwise; 2, always consider an unmarried woman innocent until *proved* guilty; 3, always believe a woman married, of the highest character living with a husband of equally high character, both solemnly assuring the medical man that no intercourse has taken place for two years, as she has been bedridden for that length of time, may bring forth a dead fœtus; 4, always believe a young unmarried woman, with abdominal tumor, of high social position and unimpeachable virtue, if she has been watched over by a platonic, abstemious young cousin of the male persuasion, while the mother went out, to be pregnant.—*Michigan Med. News.*

A New Infectious Disease.—The *Michigan Medical News* quotes from a local paper the following: "There were fifteen pairs of twins born in Port Huron during the present year, and hundreds of families who have been exposed are anxious less the disease be contagious."

A Professorship Wanted.—The following letter has been received by Dr. Cook, the editor of the *Cincinnati Medical Gazette:*

"Mr. W. H. Cook, M.D. Dear Friend Doctor I am sorrey to say I did not get to see you when at your place and to Learn of your Ill health; Hoping that by this time you are at work a gan in the class: I think I will be down to see you a gan in a short time if I well a nuff posted would like to worke in some one of our colleges next winter on materia medica or surgeory as I want to do all in my power to keep our colleges up and prospering I dont care as for the great a mount of money maid but see the Bisiness in our cause go on and Be advancing Doctor if you would hapen to have a vacant place on Either of these to Branches of studdy I will take Either one of them If I can make my Bord while at the Turm Leet me know soon in Reference to this well doctor I have a noble Practise here and am diewing as well as I could wish to do Eney where Hoping to Here from you soon I remain yours Respectfully, T. L. H., M.D."

Dr. Cheyne and Beau Nash.—When Cheyne asked Beau Nash if he had followed his prescription, his witty patient replied, "No indeed, doctor, for if so, I would have been dead." "How so?" asked the doctor aghast. "Because," said Nash, "I threw it out of the window."

Administration of Tannin.—According to a recent article by Dr. Lewin, in Virchow's *Archiv*, it should be borne in mind that when tannin enters the stomach it forms with albumen precipitates which require for their solution an excess of albumen, of lactic, or of hydrochloric acid. If the albuminate be not soon dissolved, especially if the tannin has been given in the form of powder, the solid particles are likely to adhere to the gastric walls, and produce extensive irritation of the mucous membrane. To avoid this, the tannin should be given either as a solution of albuminate of tannin or as alkaline tannate, and not in the form of a powder. A solution of albuminate of tannin is readily prepared by adding a solution of albumen to a solution of tannin till the precipitate at first formed is redissolved in the excess of albumen. This, if made alkaline by the addition of soda carbonate, is still more readily absorbed.—*Boston Med. and Surg. Journal.*

A Remedy for Trichinosis.—Dr. J. M. Baston claims to have successfully treated four cases of trichinosis with large quantities of glycerine. The treatment is based upon the fact that immersion in glycerine proves fatal to the parasite.—*Gaceta Med. de Sev.*

## THE ACTION OF MERCURY IN SYPHILIS.*

By EDWARD B. BRONSON, M.D.,
NEW YORK.

It is not surprising that the introduction among the *materia medica* of substances so potent in their modifying influence upon the animal economy as are mercury and its compounds, should have created a stir in the world of medical thought. The result has been theories without number and most incongruous, controversies the most bitter and uncompromising, and a literature so vast that it can scarcely be named.† But out of this great product what is the yield of solid fact? Is anything established with regard to the therapeutics of mercury which, in a given instance, enables us to say its action upon the disease is thus and so?

It is a remarkable fact that among remedies in common use there are none of which our knowledge is less positive than it is concerning mercury. It may be said that of all the virtues which have been attributed to it, there is not one which has not been denied; and, likewise, that there is scarcely a virtue in therapeutics that has not at some time been claimed as its attribute. But it is altogether improbable that so much labor and activity in any department of study should have been entirely fruitless. Doubtless we are now nearer the truth than ever before. It is my purpose in this paper to examine the aspects of the problem as they are presented to-day; by groping through the maze of research and speculation to seek for some tangible basis on which to found a rational theory of mercurial action. I am fully aware of the difficulties in such a task, and can hope only for a partial success. In order better to define the inquiry, as well as to limit its scope, I have taken as my objective point the action of mercury in syphilis.

Before predicating anything concerning the action of mercury, it would seem to be important to know something regarding the form in which the mercurials exist after their introduction into the body. But, unfortunately, here all is conjecture. Whether all mercurials tend to a common form, or whether each preserves its own character and individuality, are still open questions. From their effects we should infer that they all act nearly alike; but this does not necessarily imply that they are all converted into a common form. It may be said that in every mercurial compound it is the base which determines the physiological or therapeutic action; but still the question remains, How does mercury act?

The opinion prevails that in whatever way mercurials are exhibited, the absorption of them takes place after solution in the fluids of the body. How this solution is effected can only be inferred from what is known to take place outside the body. Any vital factor must be ignored. In the primæ viæ we know that the mercurials would meet various substances capable of decomposing and dissolving them. Whether the chief importance in this regard pertains to the chlorides in the stomach, the alkaline carbonates in the intestines, or the albuminoid and fatty matters, is a question which physiological chemistry has yet to decide. To enter here upon a discussion of all the various and conflicting theories would be a profitless task. There are two substances, however, capable of acting as solvents of mercury and its compounds which merit particular attention. They are sodium chloride and albumen. The reactions with mercurials of these two substances—the soluble double salts of the one and the albuminates of the other—have, as is generally conceded, an importance which pertains to no other reagents which mercury would encounter in the body.

But before going further I should call attention to the views of those who believe that mercury forms neither chlorides nor albuminates in the organism, but exists and acts solely in its reguline form. They believe that the action of mercury is purely mechanical. This theory, which was enunciated by Boerhaave, and was adopted by Astruc, has recently found an active champion in our own countryman, Dr. Clevinger,* of Chicago.

Astruc † thought that the mercury was first divided up into fine globules by the action of the heart, and was then driven out with such force and momentum that the mercury globules were enabled to penetrate where blood-cells of the same size would be arrested. Where accumulations of "blood, lymph, recrementitial and excrementitial humors were too thick and viscid," they would be broken up and dissipated by the impetus and force of the mercury globules. In this way it was claimed the venereal virus was driven out of the economy. Clevinger's theory resembles this, inasmuch as he believes mercury acts in its metallic form, and solely by its weight. The minute globules (much more minute than Astruc supposed) penetrate the finest channels in the tissues, everywhere exerting a diobstruent effect where morbid accumulations are encountered. Salivation is accounted for "by accumulations of the metal in the terminals of the dental arteries, a condition favored," he says, "by the bony covering of these arteries and their relationship with the carotids. The minute globules would find easier ingress to than egress from the dependent portion of the lower jawbone, and accumulations in the cancellated tissue, gums, and salivary glands would account for ptyalism." The writer claims that after giving mercury to a frog, he saw the metallic globules circulating in the web of the foot.

Clevinger supposes, with Jaennel, that the mercurous salts would be converted by the alkaline fluids of the intestine into mercurous oxide, but believes that this would afterward be reduced by the glucose, with the aid of the intestinal heat, to metallic mercury. The globules released would vary little in size from those in blue mass. Likewise in the mercuric salts the yellow mercuric oxide would be precipitated in the alkaline fluids, and in the presence of deoxidizing agents, such as sugar, metallic mercury is formed. In this case the precipitated globules were much finer. When a solution of mercuric chloride, which had been spread over a glass slide, was placed beneath the microscope, and then precipitated with caustic potash, a yellow, amorphous powder appeared, and then, by adding a solution of glucose, and allowing it to remain for some time "at the temperature of the body or exposed to sunlight, the particles of oxide

* Read before the Materia Medica Society, September 22, 1881.

gradually formed black points, which under high powers were recognized as mercury globules."

Rabuteau also believed that the mercury compounds were all converted into the metallic form in the primæ viæ, though his explanation is not the same as Clevinger's.

It has also been maintained by some writers that mercury, when finely divided, is absorbed through the skin in its metallic state. Oesterlin, Overbeck, and Blomberg, after rubbing mercurial ointment into the skin of rabbits and other small animals, claimed to have found globules of mercury in the deep layers of the epidermis, the rete, the cutis, subcutaneous tissue, and even in the muscles. Later experiments of a like character by Rindfleisch, Fischer, Neumann, and Fürbringer, which were conducted much more carefully, did not confirm the above results. These observers found no globules deeper than the superficial layers of the epidermis excepting the two last named, who succeeded in tracing them into the follicles of the hairs and those of the sebaceous glands. It was their conclusion that the globules were unable to traverse the skin so long as it remained intact; that before absorption took place they were converted into a soluble compound.

The experiments of Fürbringer* were especially interesting and instructive, as bearing upon the solution of mercury prior to absorption. After rubbing mercurial ointment into the skin of a rabbit he found globules remaining, not only in the superficial layers of the epidermis but also in the hair-follicles and in the ducts of the sebaceous glands. Furthermore, it was observed that in the course of a week these globules had diminished in number. Thus far his results coincide with those of Neumann, who also found globules in the follicles, and noted a gradual diminution in them, till, at the end of four weeks, they had entirely disappeared. But Fürbringer made another very curious observation, which we cannot but regard as having a very important bearing upon the question with which we are concerned. Many of the globules, especially the smaller ones, had lost their metallic lustre as well as their smooth, rounded contour, showing, instead, a roughened or jagged outline. In pursuance of this line of investigation he then prepared an emulsion of mercury in mucilage and glycerine. The globules were exceedingly small—most of them being smaller than blood-cells. With this emulsion he injected the jugular or femoral veins of rabbits. After a short time blood was taken from the vessels of the neck, defibrinated, and the blood-cells were allowed to settle, leaving a clear serum above. This serum, which was ascertained to be perfectly free from metallic mercury by Schneider's electrolysis test, gave distinct evidence of mercury in solution. Globules of mercury were found in the coagulated fibrin as well as in the mass of blood-cells in abundance. Some of the globules were found entirely unaltered, others showed the same change observed in the cutaneous follicles: The bright, mirror-like centre had become dimmed or almost unrecognizable; in others, the lustre had disappeared entirely, the contour had become more angular, and finally, there were some of a deep black color, with irregular notched edges. These same forms, the writer claims, are observed in old mercurial ointment, where, as in the present case, a partial oxidation has taken place. In order to ascertain whether the presence of the soluble mercury was a consequence of the defibrination and the other processes to which the blood had been subjected, the mercurial emulsion was added to another specimen of blood outside the body. When tested then no mercury in solution could be discovered.

In the first of these experiments it might be surmised that the globules disappeared through evaporation, the minute vaporous particles penetrating the tissues unchanged, though too small to be visible with any magnifying power. Such a supposition is hardly tenable in the light of Fürbringer's second case, and, moreover, in the first case, we have evidence that something besides evaporation took place, namely, an oxidation; and if this could affect globules of appreciable size, why should it not all the more readily effect the minuter and invisible particles? Even if these minute particles should succeed in passing the skin they would scarcely escape solution in the parenchymatous fluids or in the blood.

That metallic mercury may traverse the tissues unchanged, when the globules are of considerable size, is shown in an experiment of Claude Bernard's.

This celebrated physiologist, having bored a hole in the femur of a dog, filled the medullar cavity with quicksilver and closed the opening with wax. The soft parts healed over it and no symptoms of absorption followed. At the end of three months the animal was killed, when only one-third of the mercury was found remaining; two-thirds had disappeared. On examining the internal organs the lungs were found studded with little white nodules, in the centres of which were found little globules of mercury, many of them visible to the naked eye. They were all encysted and enveloped in a pretty thick wall.

It is probable that the small globules made their way through the meshes of the connective tissue much as do other foreign bodies—needles and the like. That they were not completely oxidized and dissolved in the tissue fluids was probably due to their comparatively large size.

In this connection I refer to some further experiments by Fürbringer* concerning the effect of injecting metallic mercury beneath the skin.

These experiments were divided into three series: In the first, pure quicksilver in mass was injected hypodermically and afterward left undisturbed. It caused no pain, no salivation was produced, and no mercury appeared in the urine. In the second series mercury was injected as before, but was afterward rubbed so as to divide it in the tissues. Abscesses resulted, the pus of which contained mercury in solution. No traces, however, appeared in the urine. In the third series the mercury was rubbed up with mucilage and glycerine and the emulsion thus formed was injected. Now evidences of absorption appeared.

In these cases it is seen that when the mercury was in an undivided mass the tissue fluids had but little effect upon it, but the more it was divided and the greater the surface presented to the corroding effect of the saline fluids the greater was the evidence of absorption.

We may admit that the globules seen by Clevinger in the web of the frog's foot were really mercury globules, but of too great size to undergo immediate solution. Had they been very minute, they could not have been distinguished from drops of fat, as shown by Rindfleisch in his criticism of

* Virchow's Arch., lxxxii., 3, p. 491, 1880.

* Deutsches Arch. f. klin. Med., xxiv., 2, p. 129.

the experiments of Overbeck and Blomberg, where they claimed to have found metallic mercury in the deeper tissues.

There can be little doubt, then, that the fluids of the body are capable of dissolving minute globules of mercury, and that this solvent effect is greater in direct proportion to the fineness of the subdivision.

Now let us turn to the subject of the elimination of mercury. Here we find a series of interesting facts that are pertinent to our inquiry. Some authorities hold that mercury is eliminated through the skin only in cases of decided mercurialism. Most observers, at least, have failed to find it in the sweat. But the fact that under certain circumstances such elimination does take place, sometimes, too, in very appreciable quantities, is attested by too many writers to admit of doubt. It is a noticeable fact that in every instance the mercury appeared in its reguline form.

Dieterich* relates a number of curious cases of this sort. In two instances observed by himself, patients who had taken mercurials internally could whiten copper coins by rubbing them over the skin of the breast. He quotes the following extraordinary case. on the authority of a physician of Brunswick:

"A lady who had been mercurialized a year before, on returning from a ball found on her breast a number of black spots. When these were rubbed with the finger distinct globules of metallic mercury were formed. There were also globules in the folds of her chemise."

A very similar case is related by Salmeron and quoted by Hallopeau:†

"A patient had been treated by various mercurial preparations, which, without causing salivation, were followed by symptoms of slight mercurialism. Two months afterward he was surprised to see the skin, especially over the region of the chest, covered with little globules of mercury, easily recognizable by the naked eye. His linen (?) also bore distinct traces of them. A copper coin which was applied to the breast was amalgamed, and was shown at a meeting of physicians. The exhalation continued for three weeks."

These cases, which seem to be authentic, and many similar ones will be found scattered through the literature of mercury, would be claimed by the metallists, who believe that in the body all mercurials assume the metallic form, as supporting their position; especially since in some of these cases it is stated that the mercury had been exhibited in the form of a chemical combination—as calomel, corrosive sublimate, etc. The cases are susceptible of two explanations, both of which presuppose the intimate relation of mercury in the body to albumen. According to one, the eliminated mercury is derived from an albuminous emulsion, in which it preserves its reguline form, and whence it is liberated in the act of excretion. According to the other, the same act decomposes a chemical compound, an albuminate, and the unstable oxide of mercury, under the influence of some deoxidizing agent in the sweat or through exposure to the light, is readily reduced to its metallic form.

With regard to the salivary gland, it is a singular fact and contrary to what we should expect, considering their marked susceptibility to mercurial influence, that among the organs which eliminate mercury from the system they hold a very inferior rank. It is pretty clearly shown, however, that in ptyalism mercury is always present in the secretion. But the opinion prevails that mercurial stomatitis is not a consequence of the elimination of mercury through the saliva. It is regarded rather as a dynamic effect of the drug acting from within, an effect analogous to the production of an urticaria after the ingestion of certain kinds of food. It has also been ascribed to nervous influence, to an impression produced upon the sympathetic ganglia. It is regarded by others as a reflex effect of stomatitis. In support of this they allege that the salivary glands do not show signs of irritation as a rule, till after the gums have already been affected. This, however, is not an invariable rule. Ptyalism may be the very first sign of the mercurial influence. Hallopeau* mentions a case observed by Fournier, where salivation was produced repeatedly by mercurial inunctions without the gums showing the least trace of inflammation, and von Mering,† who experimented with small animals, states that he has several times seen salivation produced in cats in five minutes after a mercurial hypodermic injection. While the production of ptyalism is greatly influenced by predisposing causes, the most usual and most effective cause is the rapid introduction of mercury into the system in considerable quantities. The behavior of the salivary glands clearly implies an effort to eliminate an offending substance, a substance which appears to be capable of acting as a corrosive poison to the tissues, as evinced in ulceration and gangrene. It is well known that the teeth are liable to injury in all forms of mercurialism. They become discolored, are prone to decay, loosen, and may fall out. It is a noteworthy fact, however, and true as well of those who have to do with mercury professionally as of those who take it medicinally, that when particular attention is paid to cleanliness, and the teeth are frequently brushed, they often escape all injury. And not only is this so, but by the same means the liability to stomatitis may be checked. It is a matter of every day experience that patients undergoing mercurial treatment, who frequently cleanse the teeth, rarely show any oral effects whatever. These facts would seem to imply that the injury done in the mouth is due less to an irritation communicated from within than to a corroding cause acting from without. The oral secretion contains an ingredient which, if allowed to accumulate in the mouth, may act as a corrosive poison.

The so-called "mercurial teeth" which Hutchinson has so perfectly described, exhibit changes due mainly to loss of the enamel. He says:‡

"The defects produced by mercury concern chiefly the enamel, although they may, when severe, affect the dentine also. The enamel is usually deficient, and the surface of the tooth is in varying degrees rugged, pitted, and dirty. The incisors and canines are usually affected, and not unfrequently we see the enamel deficient on them all, below a line which crosses them at the same level. The appearance produced is much as if a line had been stretched horizontally across these teeth at about their middle." "The first molars" are "almost invariably affected" also.

These appearances point most distinctly to a cor-

rosive effect to which the teeth were subjected at an early age through the administration of mercury. The "line" of defective enamel mentioned, doubtless, in early childhood corresponded nearly to the line of the gums and to the part where the secretions and impurities of the mouth would be most apt to collect. The inference appears unavoidable that the effects of stomatitis are due to the elimination of a mercurial which becomes corrosive on its escape from its organic connections. Instead of an albuminoid compound, which almost assumes the character of the homogeneous elements of the body, a noxious inorganic chemical is set free to work its destructive effects. To account for the severity of these effects, it must be remembered that there is a continual irrigation of the parts with the nocent solution, not a single application. And furthermore, this solution would become more concentrated where the secretions are apt to collect, viz., at the borders of the teeth.

But it is not necessary to suppose that the mercurial set free is corrosive sublimate; other forms of mercury might easily be converted into the bichloride after their elimination, if allowed to remain sufficiently long in the mouth, and it is not improbable that sometimes this takes place. We recall the observation of John Hunter, that every mercurial, when held for some time in the mouth, became sapid, showing that a solution had taken place. Overbeck attributed the peculiar liability of calomel to produce salivation to the fact that of all preparations it was most likely to leave traces of the dose in the buccal cavity, where it would act topically by solution in the salivary fluids.

But while it is supposed that mercury may be absorbed under other forms than that of the bichloride into which it is converted, however, on its elimination, it is equally supposable that having been absorbed as bichloride, it may, under this form, be conveyed to the eliminating organ in sufficient quantity to excite a local inflammation the moment it is separated from its albuminous combination, which, till this moment, annuls its corrosive quality. Thus would be explained the cases of sudden ptyalism which occur independently of gingivitis.

After what has been said of the effects of mercury in the mouth, little need be said of the toxic manifestation elsewhere in the body. The changes which take place in the alimentary canal are not unlike in character those that the mouth presents. Catarrhal inflammation, hypersecretion, ulceration, and gangrene are their main features and owe their origin, doubtless, to the same general conditions which give rise to similar affections in the mouth.

Much valuable information has been afforded by researches concerning the elimination of mercury through the urine. With regard to the length of the period during which the elimination may continue, some new facts have recently been elicited by the Germans. It had been asserted that the elimination of mercury by the urine was entirely completed within the first ten days after treatment. Oberländer* made examinations daily, extending over long periods after treatment had ceased. He found a period of "active elimination" extending as long as eight days. Then followed periods of intermission alternating with periods of recurrence. The intervals of rest lasted sometimes as long as ten days. These alternations were followed in one case or three months. The investigations of Vajda and Paschkis indicated that the elimination extended to much later periods—in one case as late as thirteen years after treatment. From the statistics given, the presence of mercury in the urine appears to have been relatively as common at periods of several months, or even years after the treatment, as during the first eight days. These investigations then indicate that there is always an important residuum of the drug left in the body for an indefinite period after treatment. No definite relation between the length of this period and the quantity of mercury absorbed are inferable from the statistics presented. It is reasonable to suppose that in this relation both the quantity of mercury and the duration of the treatment are very important factors.

It was noted in these observations, also, that the periods of elimination were associated in most cases with a condition of increased denutrition—a condition in which there was evident increase in the disintegration of the albuminoid elements of the organism. This point had also been made before by Voit, Waller, Günz, and others. It must not, however, be inferred from this that mercury promotes tissue metamorphosis. Herman von Boeck, who examined the fæces and urine before, during, and after mercurial treatment, found no unusual waste of the nitrogenous compounds of the body. There is reason, on the contrary, for believing that such waste is retarded. When from any accidental cause such as a febrile disturbance, a local inflammation, or the operation of such remedies as stimulate the processes of disassimilation, a disintegration of the albuminoid substances takes place, mercury is liberated, and thereby enabled to escape from the economy.

Thus far our inquiry has been chiefly concerned with the changes which mercury undergoes in its relation to the body. We have sought its reactions at either extremity of its course, tracing it as far in the economy as our limited means of observation permit, both at the points of its entrance and of its emergence. Its behavior has indicated that once arrived in the bodily fluids, its condition is generally that of a soluble albuminous salt. At the same time we have seen that globules of considerable size can resist the solvent action of these fluids; that they may long remain sequestered in the tissues, which come to tolerate their presence with indifference, as in the case of other foreign bodies. Such globules may gain access to the tissues through solutions of continuity in the mucous or cutaneous surfaces, or they may be the result of a separation of the mercury from its albuminoid combination through processes of disassimilation within the body. We have seen that such a reduction may take place at the surface in the cases of mercurial transpiration through the skin; it is not impossible that a similar change should occur in the tissues. Thus, we have a reasonable explanation of some of the cases reported by the older writers where metallic mercury was found in the tissues, especially the bones, after death. In many of the cases, however, in which reguline mercury has been found in the bones, the effect of maceration or the chemical changes incident to decomposition must be taken into account. The reduction of the metal may sometimes have been the result of these processes.

We have found reason to believe that the absorption of mercury does not always take place under identical conditions. Complex forms may be produced, double chloride salts and compound albuminates. The only essential conditions to absorption

* Versuche ü. d. Quecksilberberauscheidungen durch den Harn nach Quecksilberkuren: Vierteljahrschr. f. Syph. u. Derm., 1880, 4.

are solubility and the neutralization of corrosive and irritating qualities. But is there any reason to suppose that these complex salts are insusceptible of any future change while they remain in the organism? The albuminoids are undergoing incessant metamorphosis, are constantly being disintegrated, are constantly being regenerated; old albuminates would be destroyed and new ones formed. Would it be possible, throughout these complex changes, for calomel to remain as calomel, the bichloride as bichloride, the protiodide as protiodide? How long each mercurial would preserve its identity we have no means of knowing. Any peculiarities in the action of different mercurials are easily accounted for by the varying conditions of their absorption. But there is a manifest tendency, when mercurials have been long enough in the system, to form simpler combinations. The union with the albumen or albuminoids is such that when the mercurial is severed from its albuminous connection it returns almost directly to its reguline form. In the toxic effects which are associated with elimination, we have seen that not only may a corrosive salt have been disengaged from the albumen, but that the mercurial eliminated may have become corrosive through reactions taking place *in situ*.

I consider, then, that the ultimate state of mercury in the organism—that is, in its active, its pharmaco-dynamic form—is one of intimate and direct union with the albumen. Here it is not a question of globules in emulsion, but rather of atoms in chemical union. So soon as anything which could be called globules is present, we have simply an extraneous, inert body. I can conceive that mercury becomes as much a part of the albumen as is its component nitrogen: what was a nitrogenous body becomes also a mercurialized body.

We now turn to the therapeutic action of mercury in syphilis. At the outset I assume that the curative power of this action, whatever the latter may be, will be admitted without argument. The vagaries of such extreme antimercurialists as Hermann, of Vienna, who asserts that syphilis, in its chronic form, is only hydrargyrism, need not here be discussed. But granting the controlling influence that mercury exerts over syphilis, how is this influence explained, in what manner is it most available, and has it no countervailing disadvantages?

Though the action of mercury in syphilis has long been a field for speculation, we labor still in a *terra incognita*. Among the many theories proposed, one has already been alluded to, namely, the mechanical theory. The objections to it are implied in what has already been said.

Another hypothesis of the action of mercury in syphilis stands as a corollary to the germinal theory of the disease. In view of the well-known destructive effect of mercury upon low forms of life, it was supposed that in syphilis the action of the drug was more effectively exerted upon the germs of the disease than upon the more highly organized bodily tissues. The disease-germs succumbed while the higher vitality of the body resisted. Such a theory is expounded by Beale. Hallopeau * cites an experiment with vaccine virus performed by Chauveau, in which it was shown that when the virus was mixed with a one per cent. solution of mercuric chloride its virtues were lost and its inoculation was without effect. In referring to this experiment Hallopeau makes the suggestion that mercury may act in a similar manner in the body in destroying "the specific properties acquired by the tissue elements in virulent and infectious diseases." Were it possible to charge the body to the extent of one per cent. of its weight with corrosive sublimate, this might be true; or were it shown that mercurialized subjects could not be inoculated with vaccinia, the argument would have been more cogent. Workers in quicksilver are not exempt from parasitic diseases (Kussmaul), nor does mercury, however thoroughly administered, prevent syphilitic relapses. Were this theory correct, the principal effect of mercury in syphilis would be to prevent manifestations of the disease from occurring, while on the contrary its greatest influence is evinced on the manifestations after they have occurred.

It was the opinion of John Hunter that mercury induced a condition in the economy which was *incompatible* with the disease processes of syphilis. A diversion was created under the influence of mercury which preoccupied the system and held the syphilitic action in abeyance. In other words, mercury was an antidote to syphilis, controlling it through its own pathogenetic effects. Hahnemann sought from this theory to derive aid and comfort for his doctrine of homœopathy, but instead mercury and syphilis became a stumbling-block to his disciples. The latter now admit that the homœopathicity is not perfect, that it is often necessary to resort to "the physiological and destructive influence" of the drug to effect any change in the disease (Hughes).

Though the antidotal theory derived from Hunter has been very generally adopted, it is not a theory that explains much, nor one which is based upon any very definite facts. There is little in the physiological effects of mercury which would suggest its selection as a specific for syphilis more than for tuberculosis or cancer. But the fact that in practice it has rendered good service as a "working theory," doubtless implies some approximation to the truth. It is chiefly believers in the antidotal influence of mercury that advocate prolonged mercurial treatment. To what extent the treatment should be prolonged the hypothesis of Hunter affords no response.

There is still no inconsiderable number of physicians who, though far from being antimercurialists, refuse to admit that the prolonged use of mercury, even in small doses, is a matter of indifference to the patient's health—that it is not introducing to the economy another enemy to fight the one already there. There are still many adherents of Virchow's so-called "Dispositionslehre," the belief that "a decided course of mercury tends to engender a certain irritability in the body, a disposition to inflammation and so indirectly to the development of specific growths." Others believe with Fournier that the only safeguard against the dangers of syphilis lies in the almost uninterrupted administration of mercury for from two to four years. How are we to reconcile such diverse opinions?

The proposition that mercury can predispose the system of a syphilitic subject to the development of the later lesions of syphilis, is one not easily established. The statistics of Boeck and Julien, bearing upon this point, do not bring us to any satisfactory conclusion. We are more impressed by the general fact that cautious and experienced observers do evince a certain suspicion of mercury in long-continued doses and reserve its use for the more serious cases, continuing it only so long as the symptoms demand. To be sure these are simply

* Loc. cit., p. 156.

impressions; but what more have we to assure us that the perils of syphilis demand a treatment continued in every case uninterruptedly for years? Where have we any satisfactory proof that cases so treated do better than the average? It is simply a question of impressions, a question which is competent to any individual judgment to decide.

It is claimed that a vindication of the method of prolonged treatment has been found in some recent experiments, showing that not only may mercury in small doses be administered for protracted periods without detriment to the health, but with decided benefit. The much-maligned drug has been elevated to the rank of a tonic. The title is not a new one, however. Among the older writers it was so classed not infrequently. Murray, in his materia medica published nearly sixty years ago, classes mercury, together with iodine, arsenic, copper, etc., under the head of mineral tonics. But the term was then used in a somewhat different sense. It was supposed that by virtue of a stimulating influence, which was diffused throughout the economy, the drug excited all the vital functions to greater activity, increased the various secretions and excretions, and so enabled the system to cope more successfully with disease or to expel morbid intruders. It was not a tonic in the sense of a reconstituent, an analeptic; though it incited the vital forces to battle, it furnished no sinews of war. But now, on the other hand, mercury is presented as a tonic which actually increases nutrition, restores wasted tissue, and produces plethora. Trousseau tells us that we have but one such tonic in the materia medica, and that is iron. The circumstances which gave birth to the modern theory of the tonic action of mercury are as follows:

In 1869, Liégeois,* having been struck with the improved appearance which syphilitic patients presented that had been treated by hypodermic injections of corrosive sublimate, instituted some experiments to ascertain whether this improvement was owing solely to the effect produced upon the disease. Several non-syphilitic patients were subjected to the same treatment, and the result showed an average increase in weight of 3,662 grammes. Experiments made upon rabbits showed similar results. Of two rabbits, one, which was given sublimate injections, gained in about two months 150 grammes; while the other, not so treated, had in the same time neither gained nor lost. Another rabbit, that was pregnant, improved under the treatment, bore its young normally, and suckled them. One of these young, to which the sublimate injections were given, increased in weight more rapidly than did the others not so treated. Wilbouchewitch,† of Moscow, varied these experiments by observing the effect of mercurial treatment, in syphilitic patients, upon the number of the blood-corpuscles. His results differed from those of Liégeois, inasmuch as he found that while the first effect of mercury was to increase the blood-globules, this increase was followed by a later decrease. This difference in their results is accounted for by Keyes from the fact that Wilbouchewitch used rather large doses, which might have had a "toxic effect." Liégeois had maintained that it was only in very small doses that mercury acted as a reconstituent agent, while the larger ones caused denutrition. Keyes* used somewhat smaller doses than Wilbouchewitch, and found that the globules continued to show an augmentation above the average number in health for as long a time as the treatment was continued—in one case for eighteen months. Eight syphilitic patients, that had been taking the protiodides of mercury for different periods, showed an average gain of nearly five million globules over what was estimated as the average for a given space (1 c.c.) in a healthy man. In two instances the effect of mercury was tested on healthy subjects—in one case for four months, and in the other for four weeks. In both cases there was a marked increase, corresponding to the effect observed in the syphilitic patients.

The effect upon lower animals of small doses of mercury continued for long periods has recently been investigated very thoroughly by Schlesinger.†

Animals of equal size and weight were taken, and kept under observation sufficiently long to ascertain that they were fit subjects for comparison. The blood-globules were counted with the hæmatometer, after the method of Hayem and Nachet (the same employed by Keyes in his experiments), every day, and at different periods of the day. Quantitative tests were made also for hæmoglobin, and the urine was carefully examined each day for urea. When two animals had been found which yielded like results the experiment with mercury was begun. To one of these two animals a small quantity of a solution of corrosive sublimate with chloride of sodium in distilled water was administered in the food daily for several months. Rabbits and dogs so treated showed, by comparison with others fed in the same way, but without mercury, a general improvement, increase in weight, in the number of blood-globules, and in the amount of hæmoglobin. Sheep, goats, and hens did not improve. The best results were obtained with dogs. A bitch which had taken the sublimate solution for four months was killed and examined. No very marked changes were found, excepting abundant deposits of interstitial fat. The kidneys showed a large amount of fat in the straight tubes, in which it appeared in large drops. The glomeruli as well as the interstitial cellular tissue were intact. The muscular fibres of the heart were unaffected, but there was abundant fat in the interstitial connective tissue. In the liver there was scarcely a trace of granular fat, but "much yellow pigment." The cells were noticeably "homogeneous," and had a peculiar lustre, as in amyloid degeneration. Another dog was then treated in the same way continuously for a year. During this time its weight increased ten kilogrammes, and the blood-globules from 9,000,000 to 12,000,000 to the cubic centimetre. There was no alteration in the amount of uric acid, and the urine never contained either albumen or sugar. At the end of the year, the dog, having meantime been confined in a large open cage, was let loose and allowed to run about, the sublimate being continued as before. The effect was to make the animal ill. It appeared indisposed, and a diarrhœa set in which lasted for fourteen days. The weight fell, and the number of the blood-corpuscles underwent a marked diminution. The animal recovered, how-

ever, without stopping the medicine. It was then killed and examined. The changes found resembled those in the case above, but in a much higher degree. The deposits of fat were mainly interstitial. The muscular fibres of the heart remained unaffected, and there was nothing abnormal upon the valves; but the commencement of the aorta, for the extent of two centimetres, had undergone atheromatous degeneration. The liver-cells contained numerous fat granules, though retaining their normal shape and size. The straight uriniferous tubes were in a high degree of fatty degeneration, though the glomeruli and all the renal vessels remained intact.

To what conclusions do these experiments lead us? Is the point established that mercury is a reconstituent tonic? That effects are produced under its influence which were not suspected before, we must admit. The fact cannot be gainsaid that mercury in small doses is capable of increasing the bodily weight and the number of the red blood-globules. But does that make it a tonic? Has it been established that it promotes the processes of assimilation; that it imparts organic vigor and vital force? Are we sure, even, that the increased number of blood-cells is the result of improved hæmatosis, or that the added weight is evidence of better health? The products that entitle iron to its reputation as a tonic—the heightened vigor, the elevated animal temperature, the augumented excretion of urea, are wanting. There is increased or accumulated material, but is there any corresponding increase of energy? The larger number of blood-cells implies that fewer are destroyed than in the normal condition. The accumulated fat betrays a sluggish metamorphosis, a lessened oxidation; the vital movement is retarded. The pathological changes which a year presents may be insignificant, but they are greater than after four months. Would they not be greater still after two, three, four years?

Weighing all the foregoing reflections together, do we not gain some intimation of the action of mercury in syphilis? The chief characteristic of syphilis is a tendency to hyperplastic cell-growth. In every lesion of the disease, properly so called, this is the cardinal factor. The effect of mercury is to check this hyperplasia. It does this by imparting to the cells some quality which restrains their morbid activity, and predisposes them to retrograde metamorphosis. It does not act by increasing waste, by denutrition, but by retarding growth; nor does it aid repair. The mercurialized cell performs its vital movements with lessened alacrity; its tendency to respond to the irritating principle of the disease is diminished. Thus, we see, that mercury given before the secondary manifestations appear delays their appearance and often moderates their intensity. Kussmaul states that he has never known an instance of a worker in quicksilver *acquiring* syphilis, either primary or secondary, so long as he was actually suffering from mercurialism. But, to obtain this inhibitory action of mercury, the organism must be well charged. To this end, it is not large doses that are required, but absorbable ones. The drug must be given in the form in which the largest proportion of mercury will be appropriated by and assimilated with the albuminoid elements of the body. All else is simply waste. Nor is it necessary to induce toxic effects. Salivation may show that the blood is surcharged, but not that the organism is saturated. When each cell and fibre has received its quota of mercury, when all the tissues have been mercurialized, the body is in a state to resist the syphilitic action. But since elimination is going on constantly, in order to maintain this state of resistance the treatment must be more or less prolonged. For the remedy does not reach the cause—the active principle of syphilis—it tends only to annul its effects. But there comes a time when tissues so abnormally constituted no longer return to a condition of health. The prolonged disturbance of the normal vital movements is followed by a permanent derangement of nutrition—a true cachexia. Compared with the perils of a grave or malignant form of syphilis, the dangers that attend the prolonged use of mercury may be insignificant. There are many cases of syphilis, however, where we cannot afford to entirely ignore these lesser dangers of the cure, which may, possibly, become worse than those of the disease.

123 West Thirty-fourth Street, N. Y.

## THE CHINESE OPIUM-PIPE AS A THERAPEUTIC AGENT:

### With a Brief Study of the Manner of Using it, and the Results of the Habit when Once Formed.

By H. H. KANE, M.D.,

New York City.

About two years ago, Reginald Thompson, of London, Eng., kindly sent me a paper of his on "Opium Inhalation in the Treatment of Various Pulmonary Diseases and Insomnias," * by means of a cigarette made of bibulous-paper, nitre, tobacco, and opium,† he obtained some excellent results from an amount of opium hitherto considered wholly inoperative.

He commenced with cigarettes containing $\frac{1}{8}$ gr. of opium, but had to reduce the amount to $\frac{1}{64}$ of a grain, as the former produced dizziness in three healthy men. He obtained hypnotic, topical, and general sedative and anodyne effects from those containing $\frac{1}{64}$ gr., and as but about one-half the smoke in ordinary smoking enters the lungs, he calculates that the patient really received but about $\frac{1}{128}$ gr.

Just after receiving his paper, I made up a number of these cigarettes and proceeded to repeat his experiments. The results obtained were not fully satisfactory, owing to the fact that the smell of the burning paper was so rank, despite the tobacco and nitre added, that the patients complained of throat-irritation, and were often compelled to cough. Hence, full and deep inspiration was impossible. Furthermore, the tobacco and nitre, although present in but small amounts, rendered the results of the experiments less certain, for if $\frac{1}{128}$ gr. of opium, when deeply inhaled, was found to exercise so rapid and powerful an effect, it might with perfect justice be conceded that nitre, a drug long used in spasmodic pulmonary affections, would, when its fumes were deeply inhaled, also produce an effect of some kind.

In certain instances, such as the irritative cough

* Practitioner, 1877.

† These cigarettes are directed to be made as follows: Swedish filtering-paper is cut into pieces 4 x 2½ inches, and floated through a solution of a fixed strength, so that each cigarette-paper contains:

| | |
|---|---|
| Potass nitratis | gr. ¼ |
| Tr. tabac. | ♏ x. |
| Ol. anisi | ♏ ½. |

After being thoroughly dried, these are medicated with tr. opii of the required strength. The tincture of tobacco is of the strength of 2½ oz. of the leaves to 1 pint of spirit. When finished, the papers are rolled into cigarette-shape on a tapering stick and the free edge caught with a little mucilage. They are then ready for use.

and insomnia of phthisis, and in spasmodic asthma, using larger amounts, however, than Thompson found necessary, the results obtained were truly astonishing *when the patient was able to inhale the smoke of the cigarette fully and freely.*

After making quite a number of experiments, I let the matter rest until a few months ago, when the advent, almost simultaneously, of two American opium-smokers at the De Quincey Home for treatment, led me to study the matter of opium-smoking *in extenso*, and I then saw that if the inhalation of opium was to be of value as a therapeutic measure, the real Chinese pipe was the only instrument by means of which it could be satisfactorily done.

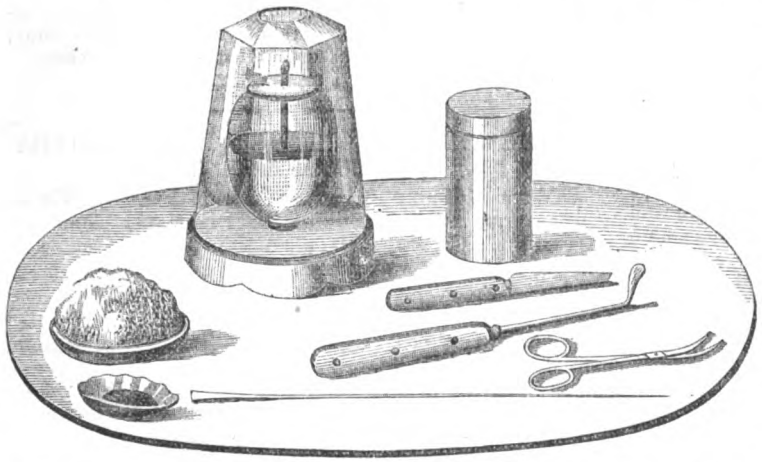

FIG. 1.—Smoker's Outfit: lamp, sponge, shell with opium, bowl-cleaners, scissors, needle, horn box for opium, and tray.

Accordingly, I procured a full outfit for smoking, which consists of the following: A pipe, a small glass lamp, a pair of scissors (*cow ten*), a long steel needle (*yen hauck*), a saucer and sponge, a box for the ashes, two bowl-cleaners, and a buffalo-horn box (*hop toy*) for holding the opium.

The opium-pipe, the origin and antiquity of which is unknown, though supposed to have first come from Arabia, consists of two parts, a stem and a bowl. The stem is usually of bamboo, one joint and a quarter, or twenty-four inches in length, and four inches in circumference. When new it is of a straw-color, but with long smoking becomes black and glossy. The stem may be of ivory, orange- or briar-wood, or sugar-cane, and is occasionally made of lemon-rind, cut, dried, and polished. The lemon-stem gives a peculiarly pleasant taste and odor to the smoke.

At about the junction of the middle and lower third, or just back of the joint, a place is hollowed out of the side of the stem and communicates with its longitudinal perforation. About this hollow there fits closely a shield of metal, usually brass, that rises in a rim about the hole. Into this is fitted the bowl. On either end of the stem is fitted a button of ivory. These stems may be plain, or ornamented with silver and gold, and variously carved. The bowl may be bell-shaped, ovate, or hexagonal. It is usually of a hard, red clay, and hollow. On its under-surface is a neck or flange by which it is fitted into the stem. To make it fit tightly, this is wrapped with strips of soft linen.

The upper surface of the bowl is either flat or sloping downward and outward. In its centre is an opening, about sufficient to admit an ordinary darning-needle. The whole pipe is called the *yen tsieng* or opium-pistol.

This is the *only* pipe in which opium is smoked, although some writers state the contrary.

The opium used for smoking is prepared in China. It is an aqueous extract, which represents fifty-four per cent. of the crude or India opium from which it is made. This crude opium contains but three per cent. of morphia as against twelve per cent. in the Smyrna opium used in this country. A special duty of $6 per pound is levied on it when coming to us.

Despite a standstill in Chinese immigration (or an actual falling off as claimed by some),* the amount of smoking-opium *used* in this country is greatly on the increase. There was an excess of seventeen thousand pounds last year over that received the year before, and as this trade is entirely in the hands of Chinese merchants, who do not form "corners" on opium, the figures show an increased demand.

This is partly explained by the fact that the vice of opium-smoking is rapidly on the increase among American men and women, there being at a low estimate at least five thousand white persons to-day indulging habitually in this practice. I am personally acquainted with nearly a hundred in this city alone. A fair daily average for each white habitu is 100 grains (16 *fun*). This, multiplied by the days in the year (365) and the number of smokers (5,000), gives us as yearly consumed by Americans, 23,762 pounds. The amount reaching us last year was 77,196 pounds, valued at $773,796.

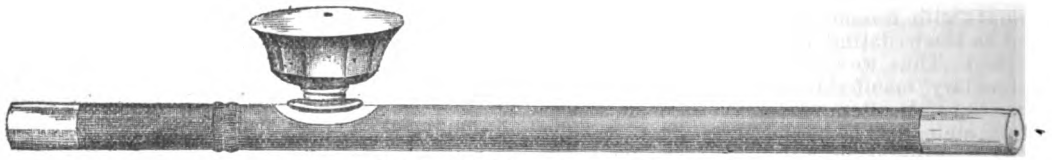

FIG. 2.—The Chinese Opium-Pipe.

The person who smokes opium *always* does so reclining, usually stretched across a hard wooden bunk covered with matting, a small stool or bevelled board serving as a pillow. Resting upon his left side, the

* Seward: Chinese Immigration in its Social and Economical Aspects. New York, 1881.

smoker takes up a little of the treacle-like mass upon the steel needle (or *yen hauck*) and holding it above the flame of the lamp watches it bubble and swell to six or seven times its original size. In doing so it loses its inky hue, and becomes of a bright golden brown color, and gives off a pleasant creamy odor, much admired by old smokers. Poor opium does not yield so pleasant an odor, is liable to drop from the needle into the flame of the lamp, and rarely gives so handsome a color, the yellow being here and there streaked with black. This process is known as "cooking" the opium. Having brought it to a proper consistence, the operator, with a rapid twirling motion of the fingers holding the long needle, rolls the mass upon the smooth surface of the bowl, submitting it occasionally to the flame, and

FIG. 3.

now and then catching it upon the edge or surface of the bowl and pulling it out into strings in order to cook it through more thoroughly. This is called *chying* the mass.

Rolling it again upon the surface of the bowl until the opium is formed into a small pea-sized mass, with the needle as a centre, the needle is thrust into the small hole in the centre of the bowl, thus leveling off the bottom of the pea.* Then, grasping the stem of the pipe, near the bowl, in the left hand, the bowl is held across the flame of the lamp to warm it; the bottom of the opium-mass is also warmed and by again thrusting the needle into the small aperture in the centre of the bowl and quickly withdrawing it, the mass with a hole in its centre communicating with the hole in the bowl, is firmly fastened upon its *surface*.

Inclining the body slightly forward, the smoker tips the pipe-bowl across the lamp, until the opium is just above the flame, when it commences to sizz and bubble. With the lips firmly pressed *against* the ivory mouth-button, the devotee inhales strongly and steadily, the smoke of the burning drug passing into his lungs. This smoke, which is returned through the mouth and nose, is heavy and white, and has a not unpleasant, fruity odor. Having finished this bolus, which requires but one long or a few short inspirations, the smoker cools the bowl of the pipe with a damp sponge, and repeats the operations of cooking, rolling, and smoking as often as is necessary to obtain the desired effect. Smokers are classed as "long-draw" and "short-draw" men, according as they consume the mass in one long or a few short inspirations. The "long-draw" is unquestionably the most injurious.

I know of no subject upon which such erroneous ideas are held, both by medical men and laymen, as that of the effects of smoking opium. It is the commonly received belief that after an habitué has smoked from one to four "pipes," he falls backward in a heavy, death-like sleep or stupor that is filled by the most vivid, extravagant, and pleasing dreams. *This is not so.* Having smoked repeatedly myself; had my nurses smoking; having had from two to six habitués at my house daily for six weeks; having watched them for hours at the smoking-houses, or "joints;" having conversed with them and with Chinese smokers; I can positively assert that such a thing never occurs, unless the drug is smoked to a poisonous excess, in which case there are no dreams at all. Upon the novice, when not smoked to excess, the effect is to produce a pleasant sense of perfect rest, followed by slight nausea, occasionally vomiting, profuse perspiration, intense itching, and that by sleep. Smoking a little more produces a decided intensification of these symptoms; more especially of the nausea and vomiting. With the habitué, or in the case of the novice who has smoked to decided excess, there is produced wakefulness, an insomnia that is sometimes distressing, being accompanied by hallucinations, delusions, and a desire to jump from a window or any high place. This happened to one of my nurses, a strong, healthy man, not given to any foolishness.

The habitué, after smoking his allowance, which varies from seventy-five grains to two ounces, feels a pleasant sense of exhilaration that merges into a condition of dreamy wakefulness. It is a state in which the devotee finds himself perfectly happy and contented. The squalid surroundings of the opium-den, the harassing cares and trials of life, are banished, and an indescribable sense of complete satisfaction takes possession of him. This waking dream, this silken garment of the imagination, will take its shape and its coloring from the most cherished and brilliant strands that run through the web and woof of his life's story. It hides the unpleasant conditions of every-day life, and gives birth to a pleasant bubble, the brilliant play of colors and misty outline of which are born of the pipe alone. As the smoker's hopes, ambitions, aspirations are, so will be the figures and incidents of his opium *dolce far niente*.

After a time, the habitué finds that the pleasant things that always came at the pipe's bidding now fail to appear, and, disgusted with the pleasureless practice, he tosses aside the pipe in disgust, only to find that at a certain hour the following day he must smoke again; not drawn to it by any fascination, but driven to it by the horrible sufferings that follow close upon the heels of any attempt to abandon it.

The effects of a single smoking upon a novice, in

* Known by some as the chandoo (*tschandu*).

moderation and to excess, may be summarized as follows:

NOVICE.

| IN MODERATION. | IN EXCESS. |
|---|---|
| Rise in frequency and tension of pulse, followed by a fall in tension and in frequency after a short period, in which both remain stationary. | Same, followed by a very decided fall in frequency, with hyperdicrotism and tremulousness. |
| Slight rise, followed by a slight fall in temperature. | Decided fall in temperature following a slight rise. |
| Tactile sensibility at first somewhat decreased, afterward increased. | Same, decided followed by a marked increase. |
| Intense itching of nose, back, scrotum, and legs. | Same. |
| Slight dizziness and nausea, with perspiration. | Great dizziness, nausea, and vomiting, with profuse perspiration. Loathing of food. Cramp-like pains in the bowels. |
| Frequent interruptions in stream of urine, with considerable waiting before stream can be passed at all. | Inability to pass urine. |
| Marked increase in sexual appetite, with erections. | Same. |
| Heaviness of the eyelids, with desire to sleep. | Sleeplessness, sometimes accompanied by hallucinations and delusions. |
| Pupils contracted. | Pupils size of pin-point. |
| Dryness of the mouth and throat. | |
| Feeling of exhilaration, with desire to straighten body and walk fast. | Feeling of quiet comfort, no desire to walk, one half of body sometimes numb, feels as if paralyzed. |
| NEXT DAY. | NEXT DAY. |
| No peculiarity. | Languid, tired, headache, constipation, stomach a little qualmish. |

This habit is like the habitual use of the drug in any other manner (mouth, rectum, or hypodermically) in the following points:

*First.*—It requires a gradual rise in the amount used to get the desired effect.

*Second.*—Pleasurable sensations do not last long.

*Third.*—The mental, moral, and physical effects differ from the other habits only in degree.*

Upon the habitual smoker we find the following effects, resulting from a prolonged use of the drug:

Loss of both desire and power for continued mental effort, tendency to lie without any good reason for so doing, vacillation, deterioration of honesty and morality, decided falling off of affection for family and friends, loss of ambition, as also of all interest in business pursuits. The temper, at first made more pleasant, soon becomes very irritable, and the individual very impatient. He indifferently watches the approach of poverty that will soon overtake those who have been so dear to him. His every hope and desire is centred in the pipe, and nothing can draw his attention from it. His eyelids are bloated and darkly underlined; his eyes now bright and glistening, and again dull and apathetic. Conjunctivitis is not uncommon. The pupils are narrowly contracted, save when the effect of the drug is wearing off and he feels the need of opium, when they become widely dilated and water profusely.

Palpitation of the heart and dyspnœa follow any marked exertion. The appetite is decidedly impaired, the mouth dry, the tongue sore, and the bowels obstinately constipated. The stools are clay-colored and coated with mucus, occasionally with blood. There is a decided loss of bodily weight. Diarrhœa sometimes follows the constipation, and is usually very severe, being attended with pain and tenesmus. Flatus forms in the bowels.

* For a full study of the effects of the habitual use of the opium-pipe on pulse, respiration, digestion, sexual apparatus, mind, bowels, etc., see Our American Opium-Smokers, by the author (now in press). G. P. Putnam's Sons.

The face may be pale and bloated, or flushed and greasy. The features strike one as having lost their former individuality. Twitching of isolated muscles is not uncommon.

The sexual appetite and power in man and sexual desire in women, at first markedly exalted, so as to justify the terms satyriasis and nymphomania, are finally almost or wholly destroyed. Cessation of the menses occurs sometimes, but not as often as with morphia-takers. Young girls and virtuous married women have often been led to smoke, and have then been ruined by men who understood these facts. Indeed, this was the chief reason for the legislation against the practice that was found necessary in California and Nevada.

In man the effect upon the urinary organs is to cause partial atony of the muscular coat, with spasm of the deep urethral muscles as the stream begins to flow. It takes several minutes to start the stream. In women no such result follows.

Upon the nervous system the effect of the practice is to produce decided irritability. Tactile sensibility is at first blunted and then increased. Staggering in walking results more from a "dazed" condition of the mind than from any effect upon the muscular system.

Upon the whole, however, it may be safely said—I having taken the worst cases as examples here—that this is the least injurious of all ways of using opium habitually. Many who have smoked for years are, beyond slight interference with function, apparently, in as fine physical condition as they were before they commenced the practice. The cure of these cases is rapid and almost painless, provided a full treatment is carefully carried out. I have cured four hard smokers in the past two months, without any difficulty whatever. One of them had been at it eight or ten years, and was looked upon as the hardest smoker (American) in this country.

The points of difference between the habits may be roughly summarized as follows:

The smoking habit differs from morphia-taking in the following points:

*First.*—There is seldom albuminuria.

*Second.*—Digestive disturbances are not so common.

*Third.*—Menstruation is less often interfered with, and the procreative power is not so markedly affected.

*Fourth.*—Insanity is not so frequent an occurrence, and disturbances of the nervous system are not so well marked.

*Fifth.*—Trophic cutaneous changes are rare.

*Sixth.*—Quasi-malarial fever is of very rare occurrence.

*Seventh.*—The symptoms of abstinence, with or without medical aid, are not nearly so severe.

*Eighth.*—After cure, recuperation is much more rapid, and after-symptoms are not common.

Financially and morally the ruin and degradation are more complete than in any other way of using the drug. An ordinary hard smoker will consume from $1.00 to $2.00 worth of the drug each day, and will spend hours over the pipe to the exclusion of everything in the way of business.

Its advantages as a therapeutic agent are as follows:

*First.*—It takes longer to form the habit.

*Second.*—It works less harm when once formed.

*Third.*—It is easier to break.

*Fourth.*—A local as well as a general effect may be obtained.

As Reginald Thompson pointed out in his excellent article, already referred to, the inhalation of opium offers special facilities for the introduction of this drug into the system. He finds that the human being, with but a single thin membrane lying between the air in the cells on the one side, and the blood in the vessels on the other, afford special advantages for absorption; and he thinks that this absorption stands next in point of rapidity to the injection of the drug directly into a vein. Such a procedure being extremely dangerous, he believes that the inhalation-method affords all the advantages and none of the dangers of intravenous injection.

As any one can at once see, such a method would be especially suited to that class of pulmonary affections where a topical as well as a general action was desired. In numerous experiments, I have found it of the greatest benefit in the insomnia of phthisis due to a frequent, irritative cough; in spasmodic asthma; and the asthmatic symptoms of emphysema and chronic pneumonia. Not only does it check the cough, but it permits of sleep in the recumbent posture, a thing that, before its use, had, in some cases, been impossible for months.

Over the other methods of using the drug it has the advantage of requiring long smoking to form a habit, and the least physical harm when the habit is formed. In many cases of phthisis it would make but little difference whether a habit was formed or not, as the patient is certain to die, and nothing so thoroughly smooths the path to the grave as opium. In other cases, its occasional use, especially if the patient did not know what he was smoking, would not produce any morbid craving for the drug.

As it takes a pea-sized mass weighing from two to six grains to affect myself or my patients *in the least*, I cannot understand how Thompson could get such decided results from the one-eighth grain. It must be borne in mind, however, in this connection, that the Indian opium, from which smoking opium is made, contains but three per cent. of morphia, as against from twelve to seventeen per cent. in the Turkey opium which we use in medicine.

The trial of the opium-pipe in the wards of one of our large hospitals would probably give some very decided results; not only in pulmonary, but in cardiac and other affections.

In catarrhal inflammation opium-smoking would be especially indicated, as it is a well-known fact amongst smokers that gleet, gonorrhœa, leucorrhœa, and nasal catarrh rapidly disappear in the smoker. Furthermore, this is about the only way of using opium alone that creates (to the novice) nausea, profuse perspiration, and decided relaxation; an effect that is reached but imperfectly by Dover's powder.

I know of one case of malarial neurosis of the heart that has been seen by Professors Loomis, Clark, and Janeway of this city, and Walsh of London, where the daily smoking of a few pipefuls of opium was the only way of using it that would control the palpitation and pain. Morphine and opium by the mouth or rectum produced constipation, loss of appetite, gloom, and despondency, all of which disappeared after he abandoned them for the pipe.

There is one point about the victims of the opium-pipe that is worthy of notice, viz.: Heretofore they have not had the excuse of excruciating pain to drive them to it, as is the case more especially with the hypodermic method, but have deliberately and wilfully placed themselves in a bondage with the disastrous effects of which they were, in the majority of instances, acquainted.

There are those who will perhaps look upon the course I am taking in this matter as opposed to that which I have written before, and censure me for trying to introduce, as a therapeutic measure, a new plan of using a drug that already numbers its slaves by thousands. In anticipation of such censure, I can only say that opium will be used in medicine so long as medicine is practised, and if we can bring forward a manner of using the drug that shall offer the following advantages, we are doing a real service to humanity:

*First.*—Maximum result from a minimum amount.
*Second.*—Rapidity of action.
*Third.*—Advantages of local effect.
*Fourth.*—Least physical, mental, and moral ill-effect from continual use.
*Fifth.*—Greatest difficulty in forming a habit when properly used.
*Sixth.*—Comparative ease with which the habit is broken.

The rapid spread of the habitual use of morphia hypodermically has been due to the placing of syringes in the hands of patients. If the physician will conceal the name of the drug he is using on the pipe and administer it himself to the patient, there is but little danger of the formation of a habit.

Finally, other drugs (their aqueous extract) may be combined in definite amount with the opium, and also used for inhalation.

191 West Tenth Street.

## A CASE OF
# PROLONGED INTESTINAL OBSTRUCTION,

### Due to Progressive Stricture at the Ileo-cæcal Junction, following Recurrent Attacks of Peritonitis.

By LEONARD WEBER, M.D.,

New York.

L. C——, eighty years of age, native of this country, bachelor, although for many years a retired merchant, had nevertheless been accustomed to a life of comparative activity. His personal habits included no vice, but he was said to be quite a gourmand, and would frequently indulge in excessive eating. Disease had been unknown to him for the greater part of his life.

Some five or six years ago, while living in the South, he contracted enteritis, and during the following winter suffered from troublesome diarrhœa. For the past few years he had been troubled, at irregular intervals, with obstinate constipation, attended with distressing flatulence and occasional attacks of local peritonitis, accompanied by severe pains, mainly in the right lower part of the abdomen. His general health, however, remained good, and he was able to undertake more or less extensive travels. In June of this year I was called to see him, and from that time until his death, which took place on the 8th of October, he remained under the professional care of myself and Dr. E. C. Wendt.

When first seen by us, his principal trouble appeared to be due to fecal impaction and paroxysmal colics. The illness from which the patient suffered had begun about eight weeks before. It appeared that the day before he was taken sick he had spent several hours in a cold and somewhat damp cellar, drawing off cider and taking copious draughts of the

same. Abdominal swelling and tenderness, flatulence, occasional vomiting, and increasing constipation, had been the most prominent symptoms. Latterly the constipation had become absolute, neither fecal matter nor flatus having been passed for several days before we saw him.

The physicians formerly in attendance had, among other cathartics, used large and repeated doses of mercurials, finally up to the point of salivation; but the impaction had not in the least yielded. Treatment by large enemata, given thrice daily by means of the long rectal tube, was at once begun. The tube was introduced to the distance of two feet or more. At first only one quart of water was used, then two quarts, and after a few days three quarts and more. In the beginning, tepid salt-water was poured into the funnel, which was connected by an india-rubber tube to the rectal instrument; then ox-gall and soap were added to the water. Abundant masses of an intensely disagreeable odor soon came away. As a rule, they had a somewhat remarkable character, resembling oyster-shell chippings in color and brittleness. Sometimes huge lumps, which looked like mangled jelly-fishes, were brought away.

The relief which followed the persistent use of these enemata was a very marked one. Moreover, untoward results of the injections were not seen—*i.e.*, no tenderness or soreness of the lower bowel was developed. The patient, who for weeks before had been confined to his bed with complete anorexia, vomiting, intense colics, and all the mental agony incident to his distressing condition, after two weeks was able to leave his bed and walk about the room. There was now but little pain and discomfort, and, although his former appetite never returned, he relished his food, and presently went to the sea-shore.

It should be stated here that repeated careful examinations of the patient's abdomen, both before and after the relief of the fecal impaction, failed to bring out the presence of a tumor. The existence of malignant trouble was, however, suspected later on in the course of the disease, for reasons presently to be explained. During a paroxysm of pain the intestines, especially in the ileo-cæcal region, could be often distinctly felt to squirm, as it were, beneath the palpating hand. They were evidently thrown into violent contractions, and seemed to rebel in their efforts to propel the intestinal contents. It was this circumstance, considered in conjunction with the other symptoms, that led to the diagnosis of obstruction from the presence of adhesive bands at or about the ileo-cæcal junction.

The subsequent history of the case may be briefly told in the following way: From the sea-shore the patient went to the mountains, changing his quarters as pleased his fancy. Recurrent colics still troubled him, but he seemed much improved in other respects. It is a noteworthy fact that what he described as a normal evacuation of the bowels took place with some regularity almost daily. The voided masses were always rather soft, and but rarely formed. To show his almost entire well-being at this time, it may be stated that while at Lebanon Springs he would often undertake comparatively long walks, and enjoy a daily drive. His relatives said that during his stay there he was quite comfortable, in excellent spirits, and appeared to be fast regaining his loss in weight. Later on, in the Catskills, he had a violent attack which confined him to his bed for days. His abdominal symptoms were said to have been as violent as ever, barring the occurrence of dejections in a natural way. From this attack he never completely rallied. To make matters worse, he had taken some cathartic pills prescribed by a well-meaning physician up in the mountains.

When we saw him for the first time on his return to the city, we were appalled at the great change for the worse which had been wrought. There was now a pronounced cachexia, utter prostration, complete loss of appetite, and almost constant pain. Anodynes had to be freely used, together with liberal stimulation. There was only occasional vomiting, and the bowels continued to move. At this time we strongly suspected malignant disease, although a distinct tumor could not be mapped out. A rapid collapse at length terminated his sufferings.

The autopsy was made by Dr. E. C. Wendt, about twelve hours after death. By request of the family it was confined to the abdomen. The peritoneal cavity contained about two quarts of a turbid, yellowish fluid, with flakes of fibrin floating in it. The visceral and parietal peritoneum was thickened, and showed considerable vascular injection, the latter irregularly distributed and especially marked about the ileo-cæcal region. Adjoining loops of intestine, and the abdominal organs generally, were loosely matted together by recent adhesions. But the evidences of repeated attacks of localized peritonitis were also found. The cæcum was abnormally adherent, but the colon appeared quite natural, and contained some formed fecal matter in its descending portion. The mesentery, especially that supplying the ileum, was so contracted by firm and dense cicatricial tissue, that the small intestine had here assumed the appearance of a rosette formed of thickened loops and coils. The color of the intestine was a dark purple in this locality. In its entire length the small intestine was loaded with mingled gas and fluid.

A firm, ring-like cicatricial constriction was externally visible at the ileo-cæcal valve. No vermiform appendix could be discovered. The cæcum and lower portion of the ileum were removed from the cadaver. On exploring the opened gut the constricted valve was found to be so narrow as to admit with some difficulty only the tip of the little finger. The opening from the cæcum into the ileum was not easily found, owing to a great looseness of the mucous membrane, which formed a finger-like projecting pouch of abnormally large dimensions, acting as a misplaced valve. In the mucous membrane of the ileum no ulcers or cicatrices of former ones were visible, but the entire coat was much hypertrophied. In the cæcum and ascending colon circumscribed patches of hypertrophic mucous membrane, resembling polypi with a broad base, were quite numerous.

A remarkable and interesting feature in connection with the small intestine was the enormous hypertrophy of its muscular layer. This was greatest at the ileo-cæcal junction, whence the thickening gradually grew less, and finally disappeared altogether. Doubtless this was a truly physiological hypertrophy, being nature's answer to a call for increased work, which was necessary to overcome the effects of a gradually increasing constriction. It illustrated the same compensatory effort that is so frequently seen in cardiac diseases, especially with those lesions which result in stenosis.

Another point worthy of notice was the great prominence of the valvulæ conniventes. Ordinarily these folds are quite indistinct at and near the ter-

mination of the ileum. But here they were far more conspicuous than in a normal jejunum. The cause of this very unusual appearance was probably the hypertrophy, principally of the muscularis mucosæ, and, in a less degree, of the entire mucous membrane.

We have here presented a case of intestinal obstruction at the ileo-cæcal junction—rare as to the completeness of its progressive development, and of great practical interest on account of the degree of exactness with which the difficulty could be located during the life of the patient.

Having removed all fecal matter from the colon in the manner above described, we found on palpating the abdomen that two or three knuckles of intestine, close to and to the left of the ileo-cæcal junction, would, from time to time, show excessively increased peristaltic action, in order to squeeze some of the contents of the ileum through the existing stricture. The greatly enlarged and thickened portions of the ileum could often be distinctly felt through the parietes as hard and firmly contracted or contracting bodies. This condition would last for a minute or two, when the abdomen would again resume its soft and doughy condition, until the next effort at propelling the contents of the ileum into the colon would take place. The colon we had cleared of fæces, and found free from obstruction; the increased peristaltic action of hypertrophied intestine was invariably found to occur in the lowest part of the ileum. Hence we concluded that the impediment must be at the ileo-cæcal junction.

The patient having had repeated attacks of local peritonitis, with persistent pain in the right lower part of the abdomen, it seemed quite probable that cicatricial tissue was compressing the bowel, either in the shape of a strong false ligament or else as a more or less circular band. As already stated, it subsequently proved to be the latter.

Throughout the varying aspects of the case we still upheld this diagnosis, although a possibly malignant disease had to be thought of toward the close of life. The palliative treatment alone resorted to, was shaped in accordance with our diagnosis. Thus, fæces were never allowed to reaccumulate in the colon after the impaction had been successfully relieved. Moreover, cathartics were never given by the mouth, since they must naturally increase the patient's sufferings. Acting on these principles, then, we were able to greatly relieve the patient's pain and distress, and at least render the last four months of his life as comfortable as was possible under the existing circumstances.

136 West Thirty-fourth Street.

A Cincinnati Health Problem.—There are half a dozen distilleries in the western part of Cincinnati, where cattle and hogs are fattened by the thousands on the warm meal-slops from which the alcohol has been obtained. These establishments give rise to very offensive odors, and it is proposed by the Board of Health to remove them, on the ground that the odors are injurious to health. The vital statistics of the city, however, show that there have been fewer deaths in the district in question since the pens were built than there were before, and fewer than there are in the cleaner portions of the city, which are sought for their supposed healthfulness. This is an anomaly that is hard to explain, but it seems to be well established. In consequence, it is something of a problem what the Board of Health has a right to do.

# Progress of Medical Science.

The Systematic Weighing of Infants.—Dr. H. C. Haven's paper (*Boston Medical and Surgical Journal*, September 8, 1881) contains some valuable hints on this subject. The following directions are given: "A balance responding to two or three grammes—almost any in ordinary household use will do this—a set of weights, preferably metric, are the necessary instruments. The child should be weighed as soon after birth as practicable, being dried and wrapped in a piece of warm flannel. The weight of this should be previously ascertained, or, if always used, may be disregarded, being a constant factor, and not affecting the results, except in the slight original addition. During the first eight or ten days the weighing should be daily. The existence, persistence, and termination of so-called physiological loss is thus determined. The original weight should be regained from the fifth to the eighth day. After this, weekly weighings for the last five months, and later, fortnightly will suffice. The best time is in the morning, when the child's toilet is usually made. This gives slight additional trouble. The daily gain should be about twenty-five grammes for the first five months, at which time the weight at birth should be doubled. After this its gain gradually decreases to about ten grammes at the end of the fifteenth month, when the initial figures should be quadrupled. These numbers are the mean of a very large number of French observations, and have the demerit of being too exact. In general, however, the average daily gain in the first few months should not be below twenty grammes. If so, the child is badly nourished, sick, or going to be. There are exceptions to this rule—the gain being sometimes less, sometimes greater. It is always, however, in direct proportion to the original weight. If this is very small, the gain may be correspondingly small. The technical difficulties of carrying out this method are slight—certainly in any institution they would be—and any mother or nurse of ordinary intelligence can be trusted to secure accurate results.

The advantages gained by this method are many. In the treatment of disease we can tell with certainty whether the desired results have been attained; exactly what food—usually the most important of all treatment—is best suited to the child; we can tell in the wasting diseases of children where, often, the struggle for life is severe, if we are gaining or losing ground; if the food, whether milk of mother, nurse, or animal, or some one of the numerous preparations, affords sufficient and proper nutriment to the babe. The scales give us information far more reliable than the intelligence of the mother, the education of the training-school graduate, the experience of the monthly nurse, or even the experience, education, and intelligence presumably combined in the physician himself.

Three Cases of Sudden Deafness from Syphilis.—Dr. Samuel Sexton (*American Journal of Otology*, vol. ii., p. 301), referring to a former paper on this subject, published in the *American Journal of Medical Science*, July, 1879, says that he still, in opposition to some writers, retains the belief that the principal lesion is confined to the transmitting structures of the middle ear. In this belief he is in accord with the late Dr. F. J. Bumstead, who ex-

presses himself to the same effect in the recent edition of his work on venereal diseases.

The first case given by Dr. Sexton was that of a man, forty-five years of age, who gave no distinct history of syphilitic disease, but who showed scars which were declared by several experts to be those of syphilitic lesions. Two years and a half before the time at which he was first seen by Dr. Sexton (September 19, 1876), the patient began to suffer greatly from pains in the head, sometimes extending down the back of the neck and spine. These symptoms, together with vertigo, lasted six months, when an attack of hemiplegia occurred, affecting the whole left side of the body. Bell's palsy on the left side was also present. Following this attack, there was complete deafness of the left ear, whether occurring suddenly or not could not be ascertained. Under the use of the faradic current, the paralysis gradually grew better; the vertigo, however, continued. On November 15, 1875, about one year subsequent to the above, while walking in the street, feeling a little dizzy, he suddenly experienced deafness in his right ear, coming "quick as a flash." He was now absolutely deaf. He was soon after admitted to the hospital, where he remained six months without improvement to his hearing. During this time he had neither pains in the head nor hemiplegia, but he had Bell's palsy of the right side of the face. When examined by Dr. Sexton, the patient still suffered from vertigo and staggered when walking. He had pharyngitis, and the tympanic membranes were lustreless and contracted; when shouted at he could hear a voice, but could distinguish no words. By means of tissue conduction through bone, muscle, etc., he could hear a vibrating tuning-fork. The drums could be inflated.

Ophthalmoscopic examination showed the eyes intact. The air in the external meatus was alternately rarefied and condensed by Dr. Sexton's instrument for this purpose, with the hope that this method of gently but firmly causing oscillations of the conductive mechanism would possibly, in some measure, break up the adhesions; but all these efforts were unavailing. Phosphorus and bromide of potassium were given without much effect, and, later, iodide of potassium in five-grain doses thrice daily, but without marked benefit.

The second case was that of a man, forty years of age, who, three months after having had a chancre, which had been followed by general symptoms relieved by treatment, caught cold and suffered from Bell's palsy. Six months after the initial lesion, and three months after the palsy, he became suddenly deaf, subsequently suffering much with noises in the head and vertigo. On examination, pharyngitis, with the same condition of the hearing as in the first case, was observed.

The third case was that of a mulatto sailor, thirty-one years of age, with an obscure history of syphilis, probably dating back some six years. Fifty days before he was seen by Dr. Sexton, he had suddenly become deaf, and at the same time began to experience frontal headache and vertigo. On examination, both ears were found affected; there was pharyngitis with naso-pharyngeal catarrh. He could not understand anything spoken or even shouted. Intensely loud tones of high or low pitch were heard, and heard better when he was in the noisy streets. He could hear his own voice, and could sing in tune. Tissue-conduction existed for the tuning-fork when placed on the skull. Noises in head very pronounced. The meatus were found large, hyperæmic, with a rather dry and glairy look. The drumheads did not look thickened, but looked humid. There appeared to be a ring of hyperæmic tissue about the drumheads. The membranes were retracted; especially the right one. The patient was placed on twenty-grain doses of iodide of potassium, twice daily, with inunctions of mercurial ointment, followed later by the mixed treatment internally, under which the hearing increased, so that he could, after a month, hear and understand loud voices at a distance of six feet or more in the right ear.

Dr. Sexton remarks regarding the pathology of this ear affection, it may be surmised that granuloma, a circumscribed, small, round-cell infiltration, takes place within the tympanum; that the invasion is rapid; and that the conductive apparatus is prevented from performing its movements by the particular manner of fixation that occurs. It is doubtful if our present means of pathological study could definitely determine its seat in all cases. In cases one and two, the oral and pharyngeal symptoms are worthy of note as showing the probable existence of hyperæmia of the drums, from reflex sympathy, previous to the syphilitic invasion.

Dr. Sexton explains why antisyphilitic treatment was not used in the first two cases, and calls attention to the improvement gained thus in the third.—*Archiv. Dermatology*, July, 1881.

Primary Cancer of the Pancreas.—Kernig reports the following case: T. T——, a woman, fifty-three years of age, had been suffering for four months from alternate constipation and diarrhœa, with gradually increasing shortness of breath. When admitted into the hospital, on May 4, 1880, the patient was slightly emaciated and intensely jaundiced. The area of liver dulness was considerably enlarged; the lower margin of the viscus was distinctly felt two fingers' breadth below the free border of the ribs, and, though hard, was perfectly smooth. Slight œdema of the feet and abdominal wall, and moderate ascites were also present. As far as could be ascertained by physical examination, the lungs and heart were healthy. Bowels costive, no vomiting nor epigastric pain. The urine contained a large amount of biliary coloring matter. Pulse, 84; respiration, 24; temperature, 38° C.

After the administration of castor oil, the bowels moved several times and continued regular, but the dejections were always clay-colored. At the same time the ascites diminished, and the abdominal parietes becoming very lax and permitting of a more thorough exploration than had previously been practicable, a hard, uneven tumor, of the size of a small apple, was plainly felt deep down in the abdominal cavity in the median line, between the navel and the margin of the liver. The tumor seemed to be quite firmly attached to the posterior abdominal wall, and did not follow the movements of respiration.

Taking into consideration the intense icterus, the deep seat of the growth, the fact that it was not connected with the liver, and the absence of vomiting and epigastric pain, a diagnosis of carcinoma of the pancreas was made. It was, unfortunately, neglected to ascertain whether the fæces contained an excess of fat, nor was the urine examined for sugar. The further history of the case may be briefly summed up as follows: the ascites for some time continued to decrease, so that the position and shape of the tumor could be more accurately ascertained; it was oval, the longer diameter lying

transversely. Later, the ascites again increased to such an extent that the swelling could only be felt with the greatest difficulty. The urine constantly contained biliary pigment, was free from albumen, and varied in quantity from seven hundred to sixteen hundred cubic centimetres, reaching the latter figure only at the time that the ascites was passing off. The temperature was usually subfebrile, fluctuating between 38° and 38.5° C. in the evening, and between 37.3° and 38° C. in the morning. Toward the close of the disease, it became lower, even subnormal (on the day before death it fell to 34.8° C. in the morning and 35.6° C. in the evening). Progressive emaciation set in, and finally, on June 10th, the patient died comatose.

At the autopsy a neoplasm was found occupying the head of the pancreas, and adherent to the stomach at its pyloric extremity, and to the whole of the duodenum, without occasioning, however, any perforation of the mucous membrane. Four small and numerous minute secondary deposits were found in the liver, as well as a thrombus of the same nature in the portal vein. A short distance above its junction with the duct of Wirsung, the common bile duct was completely enclosed by the growth and almost occluded for a distance of five centimetres. Beyond this the lumen was dilated almost to the thickness of the little finger. On microscopic examination the growths were found to belong to the medullary variety of carcinoma.—*St. Petersburger Med. Wochenscrift*, February 5, 1881.

Origin and Growth of Enchondromata.—Wartman divides these tumors into two classes, those which spring from bone, and those which develop in the soft tissues. The former, which constitute three-fourths of all the cases, are usually pure enchondromata, and owe their development, according to Virchow, to some perversion of bony growth; the latter are found in the parotid gland, the mamma, thyroid gland, bladder, and lymphatic glands, and are generally mixed tumors. When composed of typical cartilage, their growth is usually slow and painless; the mixed varieties, however, are sometimes malignant. These tumors may grow from true connective tissue, in which event the fibres of the latter melt away, become hyaline and gradually coalesce, while the connective tissue corpuscles proliferate and the resulting daughter-cells (*Tochterzellen*) acquire a capsule. When the intercellular substance undergoes mucous degeneration we have myxochondromata. Again, these growths may spring from the endothelial lining of a blood-vessel or lymph-space. Finally, cartilaginous emboli, in whatever manner they gain admittance into the circulation, may become foci of neoplasm, in part, perhaps, by infecting the intima so as to induce proliferation of its component cells.—*Centralblatt für Chirurgie*, April 16, 1881.

The Relations of Lupus to Tuberculosis.—Baumgarten (*Virchow's Archives*, vol. 82, p. 397) holds that lupus and tuberculosis are essentially distinct formations. His conclusions are mainly based upon the histological appearances of the two varieties of neoplasm. Thus an almost constant feature of lupous masses consists of giant cells irregularly imbedded in granulation tissue. These are not present in tubercle. The former tissue is vascular, does not undergo caseation and is capable of direct transformation into cicatricial tissue, while tubercle possesses no vessels, undergoes cheesy changes, but never cicatrizes. Besides, according to Baumgarten, experimental inoculations conclusively prove the non-identity of the two processes, for while the transplantation of true tubercle into the anterior chamber of the eye is followed by tuberculosis of the iris and later by systemic infection, grafts of lupus produce only negative results.

Schüller's researches have led him to the opposite conclusion. While acknowledging that Baumgarten's description of the microscopical appearances of the two kinds of neoplasm, is, in the main, correct, he insists that it is true only when we compare lupous masses with tubercles of older date. If, however, we examine tubercles at an early stage of their development, as in cases of tubercular pleurisy and in recent cases of tuberculosis of the joints, we will find them histologically identical with lupous tubercles, that is, they consist of granulation tissue enclosing giant cells and provided with vessels. Again, while Cohnheim's experiments in inoculating lupus into the anterior chamber of the eye for the induction of tuberculosis have proved futile, yet Hueter succeeded in developing tuberculosis of the iris in a rabbit by the same method. From these and other arguments Schüller concludes that lupus and tuberculosis are, on the whole, identical processes, caused by the same virus, the intensity of the latter varying according to the seat and the nature of the tissues which it primarily invades.—*Centralblatt für Chirurgie*, February 19, 1881.

Scrotal Calculus.—A unique case of this affection is reported by Lippoman, in the *Wratschebuyja Wedomosti*, 1881, No. 454. The patient, a peasant, sixty-eight years old, stated that fifteen years previously he had suffered from difficulty in passing water, which finally became so aggravated that he consulted a physician, who removed from the scrotum by incision a stone weighing one hundred and twenty grammes. An urethral fistula resulted, through which all the urine passed, at first with ease, but of late with increasing difficulty. On examination a fistula was found just behind the peno-scrotal junction. All endeavors to pass a metallic or an elastic catheter per urethram were futile; only the anterior portion of the pendulous urethra was permeable. The scrotum was as large as a child's head, and was distended by a hard mass. The testicles were dislocated toward the external inguinal apertures, and were very much atrophied. On introducing a catheter into the fistula, it was arrested by a stone. On the following day an incision was carried from the fistula backward along the raphe of the scrotum, and four calculi, weighing in all forty grammes were removed. They were rough, of a grayish yellow color, showed facets, and consisted of phosphates. When placed in apposition they were as large as a goose egg. The cavity left after the operation was cleansed with carbolic acid, drained, and healed kindly, leaving a fistula, through which the patient urinated. Later he emptied his bladder with the aid of a self-made catheter, consisting of a goose-quill.—*Centralblatt für Chirurgie*, April 23, 1881.

---

Gastrotomy for Extra-Uterine Pregnancy.—On the 13th of July, Dr. Beisone performed the operation of gastrotomy at term upon a primiparous woman, forty years of age, for extra-uterine pregnancy. A living and viable fœtus was extracted. Unfortunately, four days after the birth of her child, the patient was seized with septic infection and died on the sixth day.—*Raccog. Medico.*

# THE MEDICAL RECORD:

## A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., Editor.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, November 5, 1881.

## THE AMERICAN ACADEMY OF MEDICINE.

Our esteemed friend, Dr. Richard J. Dunglison, of Philadelphia, the Secretary of the American Academy of Medicine, takes some exceptions to our recent editorial offering suggestions for the more extended usefulness of that learned body. His remarks are so much to the point, and are so deserving of consideration, that we do not regret the article which has provoked them, but rather congratulate ourselves that the enthusiastic advocacy of the claims of the Academy to recognition are so well presented. The criticism of the aims and purposes of the organization is, if we can judge from the present reply, calculated to do it good rather than harm, and so far we have reason to be more than satisfied with the outlook.

The Academy has always had our sympathy, and we have never hesitated to speak well of it when occasion required. It is, in fact, an institution which deserves more than it obtains, and which, with proper management, is destined to exert an immense influence for good, not only upon the present, but the rising generation of medical men. It numbers already among its members some of the most distinguished and influential physicians of this country, and our only concern has been, by anything we may have written, to make it still more representative and useful.

In view of the data so positively given by the distinguished secretary, we are reluctantly forced to the admission that the number of medical men eligible to membership is much below the supposed average, but still this is large enough to increase the ranks many fold of good workers and true. We are glad to learn that the initiation fee is the only one exacted of the members. On this score a very tangible objection to the management of the organization has been removed. The diploma, being only a matter of choice, does not practically incur any additional pecuniary obligation. The admission of all who have received a degree of Bachelor of Arts, instead of such as possess the Master's degree, as heretofore, certainly opens a wider door, and is a decided improvement in the proper direction.

But, admitting all these possibilities for good, there comes a far more important question to answer. Aside from the honor of membership to such a society, what tangible good accrues to the member? Certainly, more should be expected of an organization than a meeting once a year, in which an annual address is delivered and the officers elected. With due deference to the orators who have so learnedly and eloquently upheld the cause of advanced medical education, it appears that something more is needed to vindicate the claims of the Academy to recognition by the profession at large. Although it may be eminently useful to agitate in a general way the necessity for the proper preliminary training of medical men, nothing clinches an argument so forcibly or so directly as the proof of its practical application.

The time appears to have arrived when the Academy must vindicate its claim to wider recognition by other means than those employed. The proper way to prove the value of membership to such an organization is the useful work which the latter can perform for the profession.

It need not be said in this connection that the profession is now looking to it to develop the material it has at its command by valuable contributions to the healing art which shall be not only meritorious as literary productions, but valuable additions to our knowledge of the treatment of disease. There is really no reason why both these functions should not be associated with the good purposes and legitimate aims of the Academy. If such were done, there would be no need for inquiring why the organization does not grow faster and rise to its high privilege of demonstrating the value of thorough preliminary training. In no more practical way could it prove that a literary education is of the greatest value to the medical man; in no more direct manner could it settle the question that those so trained could accomplish the best work in intelligently investigating the laws of nature and in successfully applying them to the cure of disease and the mitigation of human suffering. These are the privileges of the Academy, and the Academy must arise and assert them. Let the members contribute papers on medical subjects; let them, by the investigation of such topics, prove the superiority of the higher education, and by their methods of study show the example how scientific work should be done with all the advantages of broad, general, and liberal qualifications. We submit that this is not impracticable, and will be in keeping with the best interests of the Academy and with the truest advancement of medical science. The mate-

rial is ready, and the Academy can have no higher aim than its proper development. The transactions can then comprise something more than an annual address, and its membership can swell to its proper and legitimate proportions. At present, however, aside from proving eligibility, the membership is, comparatively speaking, an empty honor, and is consequently not sought for as it would otherwise be. It can thus become an Academy of Medicine in spirit and in truth, and vindicate its claim as one of the leading medical organizations of the land. We would fain believe that this may be its ultimate aim, and that each member may have the best of reasons for being proud of its achievements as a model and progressive medical society. No one better than its secretary and other active members are able to appreciate the practical results that would attend the fulfilment of such a high mission.

THE PHYSICAL AND INTELLECTUAL STATUS OF WOMAN.

We give in another column some of the facts recently put forth by M. Delaunay, as evidencing the physical and intellectual inferiority of woman. It will be seen at once that the writer has only industriously compiled what has, for the most part, long been known to those at all acquainted with the medical sciences. The lay press, while extensively quoting Delaunay's statements, has added to them, as a rule, only expressions of incredulity or wonder, and has rarely given any intelligent criticism regarding his conclusions.

The test of a physical superiority lies as much in the completeness with which the organism is adapted to its ends, as in its strength and complexity. The whale has larger bones than man, the cockroach a stronger muscular fibre, the dog has denser blood and more corpuscles, the gorilla has a more highly developed osseous and muscular system, the donkey a lower pitched voice. The respiratory phenomena are more intense in birds than in man, the delicacy of the muscular mechanisms is greater in a number of lower animals, and the fastest trotter is Maud S. The cranial capacity of the canary bird is greater in proportion to the size of its body than is that of human beings, male or female.

We state all this only to call attention to the fact that it is not by yard-stick or scales alone that the question of physical superiority can be settled. One must ask also whether the animal is not proportionately fitted for the struggles of existence. And looked at from this point of view, the case is not such a hard one. Women can endure pain better, can lose more blood and more sleep than men. Though they eat less they assimilate, in proportion, more. Though the brain is less heavy it is less often diseased, and though woman has less bodily strength, she oftener reaches old age. So one might go on through a list of *per contras* that might offset a number of M. Delaunay's propositions. It would all tend to show, however, only that woman physically was as complexly built, and yet almost as well adapted to her environment as man. Mentally there can, of course, be but one thing said. In quickness of perception, in delicacy and strength of feeling, in unselfishness and capacity for self-sacrifice, she may claim superiority. As regards the harder intellectual traits, the dictum of Mr. Charles Reade is no doubt true: that the picked woman only is superior to the average man. Woman's mental strength lies in what she can make man do more than in what she can do herself, and the only question is whether medical societies or individuals should decide who has these fundamental qualities.

This is a question not to be lightly considered or hastily answered. But, meanwhile, it is quite generally admitted that organized efforts to persecute and crush out any apparently untenable system are unwise. The more sensible and effective plan is to offer as little active resistance as possible. It is one of the fundamental facts in politico-economical science that by paying out to the calf plenty of rope it will be sure to eventually hang itself.

NEW METHODS OF TREATING ERECTILE TUMORS.

M. Constantine Paul presented to the French Academy of Medicine, recently a child whom he had cured of an erectile tumor by vaccinating the growth. M. Paul claimed that he had devised a new method for treating this class of disorders. We are not aware that he claimed for his method of treatment any essential originality. At any rate, vaccination as a method of treating small nævi has long been known to English and American surgery. But M. Paul described a new and peculiar process of performing the operation for vaccination, by means of which he had obtained the specially good results to which he called attention. In vaccinating by the ordinary method it would be quite probable that some part of the tumor's surface would not become affected. In this case the cicatricial tissue resulting from the inflammatory action would be only developed at certain points, leaving the rest of the tumor unaffected. In order to secure uniform inflammatory action throughout the entire surface, therefore, M. Paul covers the tumor with a layer of vaccine lymph, and then through this punctures are made all over the parts desired to be affected.

M. Paul presented a case treated in this way with quite notable success. The patient was a little girl who had had a large erectile tumor on the back of the head. It was situated below the occiput, extending on the right side nearly to the ear. It was, according to M. Paul, at the same time cutaneous and subcutaneous. The vaccination pustule had af-

fected the whole part, and was three months in entirely healing. The skin where the tumor had been was then completely devascularized, but there was some erectile tissue remaining beneath it. This M. Paul believed, from previous experiences, would finally atrophy and disappear.

In a subsequent discussion upon this method of treating erectile tumors, MM. Gosselin and Blot both took the ground that M. Paul's cure was incomplete, and that in all cases where there was any subcutaneous vascularization, vaccination would be nearly futile. It could, however, cure superficial erectile tumors, and in the subcutaneous forms it would at least give a hard, strong covering to the tumor, which would prevent any danger from ulceration or rupturing with hemorrhage.

Commenting upon this procedure, M. E. Ricklin (*Gazette Médicale*) refers to another easy method of treating these tumors, which has been successful in the hands of Dr. Schrumpf. This practitioner treated several cases by bandaging and compression. The tumors were very large, but were situated either on the fore- or upper-arm. By bandaging the extremity from the fingers up, the erectile tissue was made gradually to atrophy and disappear.

## Reviews and Notices of Books.

LANDMARKS, MEDICAL AND SURGICAL. By LUTHER HOLDEN, Consulting Surgeon to Saint Bartholomew's Hospital, London, etc. Assisted by James Shuter, M.A., Camb., F.R.C.S. Third edition. 8vo, pp. 73. Philadelphia: Presley Blakiston. 1881.

THE author has adhered to his original design in describing the "landmarks" on the surface of the body by abstaining from the use of diagrams and figures. By such means he hopes to stimulate in the student a desire to make out the "landmarks" on the body itself. The work is nicely printed and is of convenient size. This edition is a reproduction of the former one. Our good opinion of the work is still maintained.

A PRACTICAL TREATISE ON IMPOTENCE, STERILITY, AND ALLIED DISORDERS OF THE MALE SEXUAL ORGANS. By S. W. GROSS, A.M., M.D., Lecturer on Venereal and Genito-Urinary Diseases in the Jefferson Medical College of Philadelphia, etc. 8vo, pp. 174. Philadelphia: H. C. Lea's Son & Co. 1881.

DR. GROSS'S little treatise does exactly what its author would have it do, *i.e.*, it supplies in a conveniently compact form practical and mainly scientific information in regard to a class of disorders which, from their wide prevalence and occasional gravity, merit the careful attention of the practitioner. Such a work can hardly fail of professional appreciation, and we have no doubt that this unpretentious little volume will be a welcome guide to the general practitioner, who must needs come in contact with just such cases as are elucidated by the author. The different kinds of impotence are first discussed, and then followed by a chapter on sterility. This is considered from three different aspects, viz., azoöspermism, aspermatism, and misemission. Spermatorrhœa and prostatorrhœa form the concluding chapters of the book.

TRANSACTIONS OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA. Third series. Vol. v., 8vo, pp. 124. Philadelphia: Lindsay & Blakiston. 1881.

A GREAT part of this volume is taken up with biographical sketches of deceased members.

Dr. Robert P. Harris contributes two exceedingly interesting papers on foot-binding in China, giving an account of the operation and its results, and illustrating the latter with diagrams.

THE PRACTICE OF MEDICINE AND SURGERY APPLIED TO THE DISEASES AND ACCIDENTS INCIDENT TO WOMEN. By W. H. BYFORD, A.M., M.D. Third edition. 8vo, pp. 674. Philadelphia: Lindsay & Blakiston.

THE third edition of this work has been considerably changed as compared with the last. There are many evidences of revision, while much new material has been added to make up for the omission of puerperal diseases and diseases of the breast, which occupied considerable space in the previous edition. The general character and make-up of the work have not changed, however. Its distinctly individual peculiarities are still preserved, giving it a special value as a useful and comprehensive guide-book to the practitioner. The whole ground, as comprehended in the title, is quite thoroughly gone over, taking the reader through the accidents to the different parts of the female genitalia, and discussing their treatment; after which the diseases of these organs and their reflex sympathies are duly considered. The illustrations are very well executed, and in many instances are artistic. Very many of the instruments figured serve the double purpose of illustrating the text and advertising one or two instrument firms. The work is well up to the times, and will continue to be a favorite with such as practise gynecological operations, or treat uterine disease from the general practitioner's standpoint.

LECTURES ON DIGESTION: AN INTRODUCTION ON THE CLINICAL STUDY OF DISEASES OF THE DIGESTIVE ORGANS. By Dr. C. A. EWALD, Lecturer in the Royal University of Berlin, etc. Translated by Robert Saundby, M.D., Edinburgh. 12mo, pp. 149. New York: W. Wood & Co. 1881.

THESE lectures, twelve in number, discuss many of the abstract questions connected with the physiological chemistry of digestion, and apply them to the needs of the advanced student and practitioner. The amount of material compressed in them is a matter of surprise to the reader, and shows the author to be a thorough master of his subject. It is a work the value of which can only be appreciated by a careful study of its contents.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—At the annual meeting, held October 24, 1881, the following officers were elected for the ensuing year: *President*, Dr. F. A. Sturgis; *Vice-President*, Dr. W. Gill Wylie; *Secretary*, Dr. Wesley M. Carpenter; *Assistant Secretary*, Dr. P. Brynberg Porter; *Treasurer*, Dr. O. B. Douglas; *Censors*, Drs. David Webster, Daniel Lewis, A. Jacobi, E. F. Ward, and E. B. Bronson.

# Reports of Societies.

## NEW YORK PATHOLOGICAL SOCIETY.

*Stated Meeting, October* 12, 1881.

Dr. T. E. Satterthwaite, President, in the Chair.

Dr. Wyeth presented

A TONSILLAR CALCULUS.

It was interesting on account of its rarity rather than its surgical importance. The patient had suffered from tonsillitis for about six months when he came under his observation. On examination he discovered a black speck just behind the anterior pillar of the fauces, and, on touching it with the probe, found that it was a hard substance. He enlarged the opening and removed the calculus presented, which was irregular in shape, and about three-eighths of an inch in diameter. After the removal of the calculus, the tonsillitis disappeared rapidly.

Dr. J. Lewis Smith said that he had met with one such case, and the inflammation continued until two calculi were removed.

Dr. Briddon thought that calculi existed very frequently in connection with chronic hypertrophy of the tonsils.

Dr. Wyeth asked whether he referred to calculi or to the cheesy masses so commonly found.

Dr. Briddon replied that in the centre of the cheesy masses calculi were usually found.

The President referred to a case of obstinate chronic tonsillitis in which he had occasion to push one tonsil backward, after which he saw the yellow edge of a foreign body, which, when grasped and released from its bed, was found to be a small calculus that had been lodged in a crypt of the gland. Marked improvement followed this trifling operation.

Dr. Van Gieson thought that these concretions did not stand in the relation of cause to effect, that is, the conditions of the tonsils produced the concretion, and not the concretion the tonsillitis. However uncommon they might be for the specialist, such bodies were not unfrequently seen by the general practitioner. He had not seen a calculus as large as the one presented by Dr. Wyeth, but had frequently found a hard nucleus in the centre of the cheesy masses removed from the tonsils.

Dr. J. Lewis Smith remarked that, in the case in which he had occasion to remove the two calculi referred to, they evidently kept up the inflammation. Although the tonsillitis produced the calculus in the beginning, the calculus, on the other hand, gave rise to secondary inflammation.

PROLONGED INTESTINAL OBSTRUCTION DUE TO PROGRESSIVE STRICTURE AT THE ILEO-CÆCAL JUNCTION, FOLLOWING RECURRENT ATTACKS OF PERITONITIS—ENORMOUS HYPERTROPHY OF THE MUSCULAR COAT OF THE ILEUM.

Dr. E. C. Wendt presented a specimen which illustrated the above condition. [See p. 515.]

Dr. Briddon asked Dr. Wendt if, in the case reported, any fecal tumor was discovered during life.

Dr. Wendt remarked that the physical signs were not well marked, although the rational symptoms all pointed to fecal impaction; still, some dulness was found in the ileo-cæcal region, and dulness was also found corresponding to the ascending, the transverse, and the descending colon.

Dr. Briddon asked if tympanites was present in the umbilical region or in the region of the colon.

Dr. Wendt replied that at first the tympanites was general. There was an enormous distention of the entire abdomen, which had even interfered with respiration, when they first saw the patient. Later, the tympanites changed its position, but, as a rule, it was most conspicuous on the right side.

Dr. Briddon remarked that when obstruction existed above the ileo-cæcal valve, tympanites was likely to be developed in the central portion of the abdomen; whereas, when the obstruction was at the sigmoid flexure, it was most evident in the colon. He further remarked that it was only in chronic cases that we were able to feel, through the abdominal walls, the coils of intestine contracting under the hand. He also thought that the thickening of the lower part of the ileum and the increased size of the valvulæ conniventes might be the result of a previous distention of the gut. There must have been considerable distention of the intestine at some time, so that the mucous membrane had been involved as well as the other coats, and when that distention was relieved, the gut emptied itself and then contracted, leaving these folds more prominently marked. He also asked if laparo-ileotomy was thought of at any time during the progress of the case.

Dr. Wendt replied that the patient, when first seen, was in such a poor condition that an operation was not to be thought of. He further remarked that the obstruction above the ileo-cæcal valve became prominent only after the fecal impaction had been relieved; that there was then no indication for an operation, and that there was only a moderate amount of dilatation of the intestine.

Dr. Briddon remarked that he was unable to understand how any condition should preclude the performance of laparo-ileotomy in a case of impaction due to contraction and that refused to yield to other treatment. He also suggested that the hypertrophy of the valvulæ conniventes might be due in part to a chronic catarrhal inflammation of the mucous membrane, such as is usually met with in such cases.

Dr. Wyeth thought that the most singular feature of Dr. Wendt's specimen was the hypertrophy of the valvulæ conniventes. Why this portion of the absorbent system should be involved, he was not able to understand. He further remarked that the valvulæ conniventes cannot be obliterated by any amount of distention of the intestine.

The President said that, in seeking an explanation of the marked prominence of the valvulæ conniventes, it would be desirable to know whether or not the intestine was in a state of contraction. If it were still in a state of intense contraction, it was easy to understand how the mucous surface might be thrown into folds.

Dr. Wendt remarked that the intestine at the autopsy was moderately distended with fluid and gas; and he further remarked that the hypertrophy of the muscular coat of the intestine extended upward for about three yards, gradually diminishing from the ileo-cæcal valve.

Dr. Wyeth suggested that the increased size of the valvulæ conniventes might be secondary to the hypertrophy of the muscular coat.

The President remarked that it was easy to believe that it might be secondary. He regarded it as

very much like the condition of the mucous membrane of the bladder when that viscus is hypertrophied in all its coats. When such a bladder is in a state of contraction the redundant mucous membrane represents an uneven surface, filling in the cavities between the muscle-bundles.

Dr. Heineman thought that Dr. Wendt's explanation was the best offered, for the reason that there was uniform thickening of all the coats of the intestine. The mere fact of distention existing for some time would not be likely to result, by subsequent contraction, in such a hypertrophy of the mucous membrane, and produce such a marked prominence of the valvulæ conniventes. He thought that the portion of the intestine presented was evidently still dilated, as could be proven by placing its cut surfaces in contact with each other, and thus restoring the lumen. We could not judge of the narrowness of the stricture from its present condition. It was well known that intestines, unless well preserved, soften very quickly after autopsy, so that a stricture which at post-mortem would hardly admit the tip of the little finger, would soon so increase in size as readily to admit the thumb. Again, with reference to the suggestion made by Dr. Briddon, that chronic catarrhal inflammation might account in part for the hypertrophy of the valvulæ conniventes, he thought that such a result would not occur from this alone. He had not seen so marked a thickening as existed in the specimen presented in any case of chronic catarrhal inflammation involving such an extent of the small intestine. In this case the hypertrophy was in the last portion of the small intestine, the duodenum and jejunum not being involved. The obstruction itself was probably the cause of the condition, and was presumably one which had acted continuously for some time.

The President was inclined to think that there was hypertrophy of the coats of the intestine, and that it was compensatory in character, exhibiting the vigorous efforts nature had made to force the intestinal contents through the stricture. Though the gut might have been found partly filled with its normal contents, and the actual lumen of the specimen greater than normal, it seemed, from the great thickness of the cut walls, that contraction had taken place, so that very great dilatation must have previously been present. Such a tube could not contract down to the normal extent, owing to the thickening of the muscular and connective tissue elements in the coats. It was in the same condition as a dilated and hypertrophied bladder which had contracted to its utmost limits, and yet was far from contracting sufficiently to expel its contents. The marked prominence of the valvulæ conniventes and their abnormal occurrence in this situation might be partly due to the increased nutrition of the adjacent tissues, partly to longitudinal contraction of the gut.

Dr. Wendt remarked that, no matter how much the intestine was stretched in this case, the valvulæ conniventes could not be obliterated.

Dr. Briddon remarked that he did not wish to convey the idea that the prominence of the valvulæ conniventes was necessarily the result of contraction in the previously dilated gut; but that the gut had been dilated he did not think there was any doubt, and the existence of the excessive tympanites during life sustained that view.

Dr. Wyeth remarked that it was stated in the books that the valvulæ conniventes did not extend all the way around the intestine, whereas, in the specimen presented, they encircled the gut almost completely.

### Intestines illustrating aggravated lesions of typhoid fever.

Dr. Wendt also presented several specimens of intestines removed from the bodies of patients who died at the St. Francis Hospital.

They illustrated excessive ulceration and thickening of the mucous membrane as a result of typhoid fever. In two cases death occurred in consequence of profuse intestinal hemorrhages, and, in a third, it was the result of perforation. His principal object in presenting them was to show by direct comparison the enormous hypertrophy of the intestinal walls which existed in the first specimen. If we remembered that the normal thickness of all the intestinal coats was commonly only one millimetre, then a thickness of one centimetre, as it here existed in the ileum near its conjunction with the cæcum, must indeed be very remarkable. He had measured the different coats of the intestine under consideration, and had found that the muscular coat alone measured from two to four millimetres.

### Cerebro-spinal meningitis.

Dr. J. Lewis Smith presented a brain removed from an adult, with the following history: A primiparous woman was confined in one of the maternity wards of the New York Infant Asylum. The labor, on August 6th, was normal. Neither accident nor complication occurred after confinement, and the woman was apparently fully convalescent, when, on the 29th of August, she first complained of severe pain in the left hip, and also in the head.

But little attention was paid to the complaint until the following day, and then it was found that the headache was intense, and that she was at times delirious. She had no vomiting, which is so common in the beginning of meningitis. On the 31st of August the vaginal temperature was 102.5° F., the pulse 120. There was no marked acceleration of respiration. She screamed often, but usually lay in a doze; the muscles of the nucha were rigid, and the head was retracted. On the first of September strabismus was observed, and there was also paralysis of the right side of the face, the mouth being drawn to the left.

Dr. Smith saw the patient about twenty-four hours before death. Diagnosis had already been made of either apoplexy or cerebro-spinal meningitis, but the symptoms pointed more strongly to the latter.

About twelve or eighteen hours before death her vaginal temperature was 104.5° F. She died after an illness of three days, and in a state of coma.

At the autopsy there was found in the meshes of the pia mater, along the base of the brain, extending forward from the pons varolii, as far as the fissures of Sylvius, and along these fissures, a purulent exudation, with a moderate amount of fibrine. The exudation was not great, but it obstructed to a certain extent the view of the brain, especially along the course of the vessels. Upon the left side of the brain the exudation extended over the convex surface of the posterior half of the hemisphere to the vertex. It was not thick at any point. Almost no serous exudation escaped when the calvarium was removed. The brain was placed in alcohol, and after it hardened a few days it was opened, and there was found an evident softening of the walls of both ven-

tricles, perhaps part of it was cadaveric. From the history of the case and the lesions found at the autopsy, Dr. Smith had no doubt that the case was one of epidemic cerebro-spinal meningitis. He then referred to an epidemic of this disease which occurred in this city in 1873, commencing among the horses of the large car-stables before it appeared among the people, and at that time it occurred in all parts of the city, but more especially among the tenement-house population, where it was very fatal. In this epidemic he observed between forty and fifty cases.

About a year ago the disease began to appear in the upper part of the city, and since that time he had seen twenty-one cases of what he regarded as undoubtedly epidemic cerebro-spinal meningitis.

During this epidemic the meningitis had been most prevalent and fatal in the tenement-house population, as it was in 1873. With reference to the etiology of the disease, there were some cases which occurred under circumstances which were especially interesting. We seldom meet with multiple cases, from the fact that, the disease not being contagious, does not spread from one to another. During the present epidemic Dr. Smith had, however, seen three cases in one family, and he also learned that a workman employed upon the premises had died of the same disease, thus making four cases in one family—if the first was a genuine case. These people were engaged in procuring heads of cattle and removing the skin, which was utilized, and the fleshy portions were sold to manufacturers of bologna sausage and head-cheese.

They had, when he made the inquiry, four hundred and fifty of these heads in their building, which was about the usual number. The building was wooden, two stories high, with a frontage of about thirty feet, and the usual depth of a city lot. As a natural consequence, more or less decomposing animal matter lay about, and the family lived directly over the shop.

It would seem that the presence of this decaying substance afforded explanation of the fact that these multiple cases occurred, whereas all the other cases which he had observed in the late epidemic occurred singly, as is the rule.

Therefore, from observations made in the recent epidemic, as well as in that of 1873, Dr. Smith believes that when multiple cases occur we are ordinarily able to trace them to exposure, to foul air, or to other anti-hygienic conditions. In the epidemic of 1873 he attended only one family, in which three cases occurred. They were of a very severe type, and the apparent cause was the dirty state of the apartments and consequent impure air.

The mother, exhausted by her incessant attendance upon the children, had allowed the soiled bedclothes to accumulate till the death of one of them. Fatigued and dispirited, she spent a considerable part of a day over these clothes in washing them, and she had hardly finished her task when the ominous headache began, and she, too, died after a short sickness. The severely afflicted Brown family, whose cases were reported by Dr. Schwalb in 1873, afforded another illustration of the effect of foul air as a cause of cerebro-spinal meningitis, at a time when the atmospheric conditions were favorable for its occurrence.

But several observations made in both epidemics show that there is an occasional exciting cause of a very different nature, to wit.: some undue mental excitement. Many who now fall victims during an epidemic would apparently escape if they led a more quiet and regular life, free from care and excitement.

He had elsewhere reported the case of a young lady at the head of one of the departments of a large Broadway store, who was anxious, and overtaxed at the annual reopening, and immediately began to suffer from the disease; and of a girl who failed in her examinations in one of the public schools, went home excited and crying, applied herself unintermittingly to her books, and before bed-time had a violent headache, which ushered in a severe form of the malady. Indeed, so frequently in his practice in both epidemics had children who were subjected to the severe discipline of the public schools been affected, that he believed that when cerebro-spinal meningitis is prevailing the studies in these schools should be made light, and the parents should not impose irksome tasks at home. In the recent epidemic, a man of thirty-two years, very industrious and of active mind, the chief partner in a large and perplexing business, had two months previously convalesced from typhoid fever. When his health was nearly established he returned to his business, which, on account of his absence, now demanded his attention to the utmost of his ability. He applied himself beyond his strength to the duties of the firm, so as to feel exhausted each night. This state of affairs did not continue long when the disease attacked him, and ended fatally in thirteen days.

During the recent epidemic he had seen and preserved records of twenty-one cases, chiefly in his own practice, but some of them were visited in consultation.

The following table gives their ages:

Under one year, 1 (aged eleven months); from one to three years, 3; from three to five years, 5; from five to ten years, 6; from ten to fifteen years, 2; over fifteen years, 4 (aged nineteen, twenty-one, twenty-six, and thirty-two years).

Thirteen recovered; eight died.

The following *résumé* gives the time during which the thirteen who recovered remained in bed, unable to assume the sitting posture, even for a short time, unless with much exertion and an increase of suffering:

1, five weeks; 2, three months; 3, ten weeks; 4, three weeks; 5, four weeks; 6, sixteen weeks; 7, five and a half months (head retracted four months); 8, seven weeks (head retracted most of the time); 9, about six weeks; 10, —; 11, two months; 12, —; 13, two months.

The active period of the inflammation in these cases appeared to be within the first three weeks, the inflammatory symptoms being more marked and the temperature at the maximum during this period. The febrile movement, as is usual in this disease, varied in different hours of the same day, but in only one of those who recovered was a temperature about 105°F. recorded, which was in the latter part of the day in the third week. The ordinary highest elevation was 103°F. to 104°F., but it would probably have sometimes been higher, except for the constant application of ice to the head and nucha.

In those cases embraced in the table in which the patients were months in bed, the emaciation and weakness were usually extreme, and the result was for weeks uncertain. Some of them would, without doubt, have perished in this state of helplessness, except for the perseverance and devotion of their mothers. The one who lay five and a half

months in bed with rigidity of the muscles of the nucha, and pain whenever moved, for nearly that time, afforded an instructive example in point.

The following *résumé* gives the duration of the fatal cases: 1st, twenty-six days; 2d, thirteen days; 3d, five days; 4th, six weeks; 5th, eighteen weeks; 6th, eight days; 7th, three days; 8th, — days.

The death of most of these patients occurred from coma preceded by intense headache, convulsions, or delirium; but the one who lived eighteen weeks died apparently from bed-sores, which, probably, might have been prevented had the mother been sufficiently attentive, and removed immediately the bed-clothes whenever soiled. Three very large sores, located over the sacrum and each hip, extended nearly or quite to the bone, and although the appetite had begun to return, and the child had become conscious from a state of semi-coma, its recovery was impossible, in its very emaciated condition, with so abundant a suppuration.

All who have witnessed an epidemic of cerebro-spinal meningitis are aware of the disastrous results of the intercurrent eye and ear affections which now and then supervene. These organs are so damaged that their functions are, as a rule, lost totally and forever. In one of the twenty-one cases, however, a boy of three years and seven months, who was two months in bed, hearing appeared to be entirely lost in the beginning of convalescence, but he now evidently hears when spoken to loudly. In one other patient only were the ears involved, and the loss of hearing has been complete. Since the ear-malady was deep-seated, there was apparently no injury of the drum, no external discharge, and no symptom except loss of hearing, to direct attention to the ear. If there were earache, it was not distinguishable from the neuralgic pains which are so common in this disease. In one case only was the eye involved—a girl of thirteen years, who died at about the sixth week. When nearly one month sick, she had violent, deep-seated inflammation of one eye, which soon completely destroyed the organ. The other eye escaped.

The result of treatment in the recent epidemic was somewhat more favorable than in 1873, when about fifty per cent. perished. Thirteen in twenty-one recovered. The treatment consisted in the free use of bromide of potassium, ergot in the beginning, with ice to the head and nucha, and the moderate and cautious employment of opiates to relieve pain and procure rest. It is in the first two or three weeks that the danger is greatest, and medicinal treatment is of most importance. Afterward the chief reliance must be on good nursing, and the use of nutritious but unstimulating diet, with a little medicine, as occasion may require.

Dr. J. C. Peters thought that cerebro-spinal meningitis occurred rarely where there was a good sanitary condition.

Dr. Carpenter referred to an epidemic through which he passed, and in which the disease attacked single patients among the best families over an area of territory two miles in diameter, and in not a single instance could it be traced to defective drainage or filth.

Dr. Van Gieson referred to an epidemic of the disease which occurred at Long Branch about twenty years ago, and at that time it was thought that the disease was transported to the city of New York; but the origin of no case was ascribed to filth. However, he supposed it to be tolerably well established that cerebro-spinal meningitis is essentially a filth disease.

Dr. Peters remarked that the sanitary condition of Long Branch was always sufficiently bad.

Dr. Van Gieson asked if facial paralysis was not a rare symptom in cerebro-spinal meningitis.

Dr. Smith believed it was. It occurred in one of the twenty-one cases which he had seen during the past year, and which recovered.

Dr. Van Gieson remarked that, with a tolerably extensive experience in this disease, he had not noticed in any case the existence of facial paralysis.

Dr. Garrigues thought that the case reported by Dr. Smith was a mixed one; that the paralysis of the right side of the face must be attributed to the changes in the interior of the cerebrum. It seemed to be a case of cerebro-spinal meningitis complicated with encephalitis. Probably the reason why Dr. Van Gieson had not seen facial paralysis was because his cases had been those of simple cerebro-spinal meningitis.

Dr. Smith believed that it was a fact that softening of portions of the brain and spinal cord was not uncommon in connection with cerebro-spinal meningitis.

Dr. Carpenter thought it was rare to find localized softening.

### RUPTURE OF THE INTESTINE.

Dr. Heineman presented three specimens of rupture of the intestine as a result of different kinds of violence.

The first was removed from the body of a boy five years of age, who, on the evening of July 21st, was last seen playing upon a wagon. About an hour afterward the other boys came and told his mother that he had been injured, and when the mother reached the child she found him unable to speak and in great pain. He was brought to the Roosevelt Hospital on the evening of the 21st, and died on the following day at eleven o'clock. At the autopsy bloody serum was found in the peritoneal cavity, and there were signs of peritonitis. There was rupture of the duodenum on its posterior surface, where it lies against the spinal column, for an extent of about four-fifths of its circumference. There were no external marks of violence upon the body, except a very slight scratch on the back. There was slight discoloration beneath the peritoneum, and on further examination it was discovered that the rectus abdominus muscle had been ruptured, and there was an effusion of blood into its tissue. There was enlargement of Peyer's patches, and also of the solitary follicles and mesenteric glands—a condition not unusual with irritation in the peritoneal cavity.

The second specimen was removed from a man who had been kicked by a horse on September 3d. He vomited immediately afterward, and had intense abdominal pain. He entered Roosevelt Hospital on September 8th, and died on the following day. At the autopsy, rupture of the ileum was found. The patient had lived with this rupture six days after the injury. Another peculiarity and interesting point in connection with the rupture was this: it was noticed by Dr. Delafield at the autopsy that the opening in the intestine looked like one made by a phthisical ulcer, and when the specimen was fresh, it could not be distinguished from that variety of ulcer. In that respect it was interesting from a medico-legal point of view. If there had been other ulcers in the intestine, and the patient had been kicked by another man instead of a horse, it might have been difficult to decide as to whether the opening in the intestine was a rupture from vio-

lence, or whether it was due to phthisical ulceration.

The third specimen was removed from the body of a young man who fell thirty or forty feet. There was intense pain and an enlarged area of dulness over the peritoneal surface, and at the autopsy a large rupture of the duodenum was found, and fecal contents had escaped into the peritoneal cavity. There was general peritonitis, swollen mesenteric glands, and enlarged Peyer's patches. The three cases were interesting from the fact that they had all occurred within the last three months.

DR. WYETH asked if diagnosis of rupture of the intestine was made in the hospital in the second case.

DR. HEINEMAN replied that it was, and that the patient was treated for peritonitis.

DR. VAN GIESON asked whether the abdominal cavity contained food or fæces in the first case.

DR. HEINEMAN replied that partially digested food was found in the peritoneal cavity.

DR. VAN GIESON thought that rupture would be less likely to occur when the intestine was empty than when it was filled with partially digested food.

The society then went into executive session.

## Correspondence.

### THE AMERICAN ACADEMY OF MEDICINE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: In the issue of your Journal for October 8, 1881, is a leading article headed: "A Suggestion for the American Academy of Medicine." As you are yourself a Fellow, any suggestion you may advance will, naturally, receive from that body respectful consideration, whether offered at the meetings or from the editorial chair. To those, however, who may not be familiar with the objects of the Academy, its capabilities and prospects, the allusions made by you are apt to create a false impression. You inquire, "Why does the Academy get along so slowly?" In reply, I may say that it is not, like the American Medical Association, a body made up largely of delegates from other societies, but that its increase of membership is dependent upon individual efforts. Each Fellow before election must sign an application for membership, stating facts as to his possession of a literary degree, and this application must be endorsed by a pre-existing Fellow. The Academy is yet young—only five years old—and is, therefore, not numerically strong—having about one hundred and fifty members—and, as in all other bodies, the active work, including the procurement of new members, falls to the lot of a few. The increase of membership has been hitherto retarded by the restrictive clause in the Constitution of the Academy, which limited Fellowship to those who had already received the degrees of A.B. and A.M.; but this impediment was removed at its recent meeting in New York, the rule being then adopted that Fellows hereafter may be chosen from those who have received the degree of A.B. or A.M. There is a large number of medical men in the United States who have received the degree of A.B., but have never applied for the A.M., and some also who have received, in regular course, the degree of A.M., as at Brown University and the University of Virginia, without having obtained the A.B. The Academy has wisely determined that the possession of either degree is evidence of a collegiate education, especially as in almost all institutions the A.M. degree has been conferred simply after three years' delay, without any additional examination. Now that the door of entrance to the Academy is more widely opened, desirable acquisitions will doubtless be made to the lists of that body.

I think you overestimate the number of medical men who are eligible; I am satisfied that they are not, as you say, "among the thousands." Having had the opportunity of making a large collection of the complete catalogues of all the graduates at various literary institutions, I have been forcibly struck with the infrequency of medical graduation afterward among the classes therein represented. One or two of the annual addresses before the Academy have endeavored to emphasize this fact. Dr. Lente, in September, 1880, showed, from statistics furnished by the former secretary, Dr. Sibbet, that out of eighty thousand persons practising medicine in the United States, less than five per cent. have the degree of A.B.; and that, leaving out of consideration Philadelphia and Pittsburg, and their counties, there are not *two* A.B.'s in each county. Of eighty practitioners in Carlisle County, Pennsylvania, including the town of that name, with its literary institution, Dickinson College, there are but two who have taken their degree. Such seems to be the experience of the profession in other parts of the world, for in a letter received by me, a few weeks since, from Dr. G. M. Beard, he states that while fifty per cent. of English lawyers and judges are graduates of some one of the great universities, and seventy per cent. of the clergymen of the Established Church, not more than *one* per cent. of the physicians and surgeons, at the highest estimate, have so graduated. Even if there were, in the United States, many medical men who are conjointly A.B.'s and M.D.'s, it might not be possible or desirable for the Academy to elect them all, for the Constitution expressly provides that each candidate for fellowship must be in good standing, or of good moral and professional character. Besides, the history of all medical societies, at their inception, has been similar to that of the Academy. The American Medical Association, for example, with at least twenty times the number of medical men eligible for membership, was many years old before it secured an imposing array of members, or before it made much headway in the favor of the best men of the profession.

So far as making itself more generally known, as you suggest, the Academy has no annual volume of transactions and no official organ, but it publishes addresses annually, and will, in a short time, issue the recent excellent address of its President, Dr. E. T. Caswell, of Providence, R. I., as well as an elaborate report on the Laws of Medical Practice in the United States and Canada, both of which will be widely distributed. The Academy is the only society, in my knowledge, which does not demand an annual fee for membership. All that is obligatory is the initiation fee of five dollars, the diploma fee being wholly optional. Your strictures upon the payment of an initiation fee, without referring to this exceptional fact, seem to me unfair, and few, I think, would agree with you that this fee is unnecessarily great. The publications for this year alone will require a pecuniary outlay which, in other societies, would be met by the annual assessment of its members. This is, so far as we are aware, the first criticism that has yet been made upon the pay-

ment at the outset of a single fee that may cover perhaps half a century of membership.

As you suggest that the Academy does not make its object or even its existence sufficiently known, and as you have the opportunity, which no other Fellow of the Academy enjoys, of giving its true objects a wide dissemination among thousands of the profession, may we not hope to have your valuable assistance in securing for it a conspicuous place in the popular esteem, and in increasing its efficiency and augmenting its membership? In conclusion I would state, for the information of the profession generally, that the following are the objects of the Academy: 1st, To bring those who are alumni of classical, scientific, and medical schools into closer relations with each other; 2d, to encourage young men to pursue regular courses of study in classical and scientific institutions before entering upon the study of medicine; 3d, to extend the bounds of medical science, to elevate the profession, to relieve human suffering, and to prevent disease.

In the furtherance of these objects and in hopeful anticipation of their future accomplishment, are united some of the noblest members of the American medical profession.

Yours respectfully,

RICHARD J. DUNGLISON, M.D.,

*Secretary American Academy of Medicine.*

PHILADELPHIA, PA., October 19, 1881.

## HOMŒOPATHIC CONSULTATIONS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your issue of October 29th contains a letter from Dr. J. B. Stair, of Spring Green, Wis., in which he criticises the position recently taken by Dr. Bristowe, on the question of consulting with homœopaths, in an address delivered by the latter at the late meeting of the British Medical Association. It may be stated incidentally that Mr. Jonathan Hutchinson, the eminent London surgeon, in an address before the same association, enunciated views substantially similar to those of Dr. Bristowe. These addresses gave rise to considerable correspondence in the English medical journals, and this correspondence the writer has followed with care and interest, and is inclined to believe Dr. Bristowe and Mr. Hutchinson are more than half right in their conclusions. Consequently, we feel compelled to join issue with Dr. Stair, as a thorough understanding and an early settlement of this question, is, we believe, a matter of pressing importance. Before commencing its discussion, however, it is expedient that there should be some mutual understanding as to the use of certain terms and phrases that will naturally be employed in its course. In the first place, Dr. S. says that a radical "difference exists between the doctrines of a regular physician and of a homœopathist." I must therefore ask the doctor to define what he means by a "homœopathist," and what by a "regular physician," and to distinctly and succinctly set forth the doctrines maintained by them respectively. This, we presume, his familiarity with the subject will permit him to do without difficulty. Awaiting the desired information, we remain,

Yours respectfully,

ETHICS.

DR. RICHARD GUNDRY has been appointed Professor of Materia Medica, Therapeutics, and Mental Diseases in the College of Physicians and Surgeons, Baltimore, Md.

# New Instruments.

## A NEW NEEDLE-HOLDER.

BY GEO. E. JONES, M.D.,

CINCINNATI, OHIO.

I WOULD call the attention of the profession to a needle-holder made by Mr. William Autenrieth, surgical instrument-maker of Cincinnati, by my suggestion, on principles entirely different from any other.

It possesses a power that no other needle-holder can claim, and is under the full control of the surgeon. It not only can be used as a needle-holder, but as a holder for other instruments, especially so by laryngoscopists, with safety, as there is no fear of it losing its grip. For the above specialists it can be made curved, although it was originally intended for gynecological work.

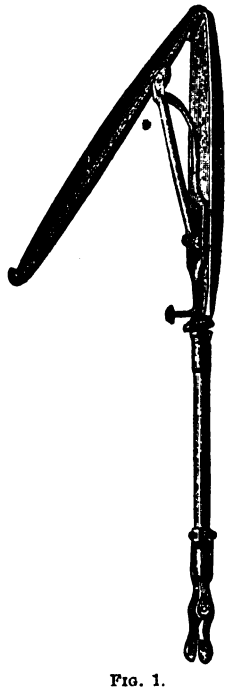

FIG. 1.

FIG. 2.

By referring to Fig. 1, the reader will see that the forceps is placed on the end of the tube; the jaws are closed by a wedge forced between the arms by a connecting rod, which is driven through the tube by a lever formed by one of the handles.

In Fig. 2 the long arm of the forceps forms one of the handles; the other arm is short, the jaws are closed by a wedge on the end of a shaft by lever-handles, the same as in Fig. 1. Either instrument, when closed, can be locked by a graduated slide under contact of the thumb. Mr. Autenrieth will also make a size suitable for the pocket-case.

THE Binghamton (N. Y.) Asylum for the Insane has been recently placed under the medical charge of a homœopathist. This is the second asylum for the insane in this State under homœopathic control.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October 23, 1881, to October 29, 1881.*

BYRNE, C. C., Major and Surgeon. Par. 2, F. O. 26, C. S., from these Headquarters, relieving him from duty in this Department, and directing him to proceed to his proper station, Benicia Barracks, California, is confirmed. S. O. 119, Department of Arizona, October 17, 1881.

HARTSUFF, A., Major and Surgeon. Granted leave of absence for one month, with permission to apply for an extension of nine months, and authority to visit Europe. S. O. 214, Department of the Missouri, October 20, 1881.

GARDNER, W. H., Capt. and Asst. Surgeon. The leave of absence on surgeon's certificate of disability, granted him in S. O. 138, June 18, 1881, from A. G. O., extended three months on surgeon's certificate of disability. S. O. 239, A. G. O., October 31, 1881.

CARVALLO, C., Capt. and Asst. Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability, with permission to go beyond the limits of the Department, and to apply for five months' extension. S. O. 108, Department of the Platte, October 24, 1881.

PAULDING, H. O., Capt. and Asst. Surgeon. Relieved from duty in the Department of the East, and to report in person to the commanding general Department of the Platte for assignment to duty. S. O. 240, A. G. O., October 24, 1881.

BROWN, P. R., Capt. and Asst. Surgeon. Relieved from duty in Department of the East, and to report in person to the commanding general, Department of Texas, for assignment to duty. S. O. 240, C. S., A. G. O.

CORBUSIER, W. H., Capt. and Asst. Surgeon. Relieved from duty in the Department of the Platte, to proceed to New York City, and, on arrival, report by letter to the Surgeon-General. S. O. 240, C. S., A. G. O.

DAVIS, W. B., First Lieut. and Asst. Surgeon. Relieved from duty in Department of Dakota, to proceed to Richmond, Va., and on arrival, report by letter to the Surgeon-General. S. O. 240, C. S., A. G. O.

## Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending October 29, 1881.

| Week Ending | Typhus Fever. | Typhoid Fever. | Scarlet Fever. | Cerebro spinal Meningitis. | Measles. | Diphtheria. | Small-pox. | Yellow Fever. |

IS GUITEAU INSANE?—As some confirmation of the view taken by the RECORD regarding the mental condition of Guiteau, we publish the following letter. It was written by J. H. Noyes, founder of the Oneida Community, where Guiteau lived for some time:

"G. W. SCOVILLE: *Dear Sir*—I see in the papers that you have named me as a witness by whom you intend to prove Guiteau's insanity. Perhaps it will save you trouble and expense if I inform you in advance that I do not believe in his insanity, and that I recollect no act or symptom of insanity in his life while under my observation. Probably I have more reason than any other man to know and detest his wickedness; but that is not insanity in any legal sense. I think that he was born with a special genius for mischief, and has had a real inspiration for it all his days; but that is not saying he is insane, unless we also call natural genius and inspiration for good things, such as invention, music, etc., insanity. I understand insanity to be unsoundness—disease of the brain; and I do not think that Guiteau has that any more than bears and lions have it. I agree with the old hymn, that such beasts growl and fight because 'it is their nature to.' With these views and the memory of my sore experience with your client, I am afraid that I should have to testify strongly against your main plea, and perhaps should be the means of sending him to the gallows, which I should sincerely regret on many accounts, and especially because his father was a dear friend to me and mine. But I must notify you that my regret would be mostly for my personal agency in the tragedy. Yours respectfully,

"J. H. NOYES.

"NIAGARA FALLS, ONTARIO, October 20th."

DR. J. J. YOULIN, a prominent physician of Jersey City, died at his residence, 130 Grove Street, in that city, October 30th, of heart disease. His age was sixty years.

A STRANGE CASE OF INHUMAN NEGLECT.—It is reported that a man who swallowed four ounces of oxalic acid, for a suicidal purpose, was left to die in a police cell at Hoboken, N. J., under the following circumstances: On Monday night last the police authorities of that place were informed that a man was lying at the Elysian Fields, apparently suffering great agony. An officer who was sent to inquire into the matter found the report to be true. The sufferer said his name was Adolphe Schaffer, of No. 179 Second Street, New York, twenty-five years of age, and that, having lost $300, he had taken four ounces of oxalic acid, with the intention of ending his miseries. He was conveyed to the police station, where Dr. Helfer was called in, who stated that the man was dying, and ordered him taken to the hospital, where he could be properly cared for, and antidotes administered. The police, instead of complying with the request, thrust the sufferer back into the cell, and there he was allowed to lie without further attention and without any effort to counteract the effects of the poison. At 8.30 the janitor found him dead on the floor. Chief Donovan, when questioned as to the affair on Tuesday, excused the conduct of the police by saying that they could not send any one to the hospital without an order from a City Physician, and that official could not write an order without permission of the Common Council. He also said that Dr. Helfer applied to Mayor Besson for the necessary permit, but it was refused, with the suggestion that the man be sent to New York, where he belonged. The explanation seems a strange

one, since the hospital is not a city institution, but belongs to the Sisters of St. Mary, is maintained by charity, and receives all classes, creeds, and colors, without the intervention of the police, and is noted in the community for the good work it is daily doing.

In view of the above circumstances, it is due to ordinary humanity that the parties who were accessory to this outrage should give a more satisfactory explanation of their conduct. It is decidedly the worst case of its kind that has come to our knowledge, and should receive the most thorough investigation.

THE GARFIELD HOSPITAL.—In furtherance of the project to erect and maintain a national hospital in memory of President James A. Garfield, the executive committee having the matter in charge have issued an appeal to all pastors of churches to aid in the good work. The institution is to be established in the District of Columbia, and is to be known as the Garfield Memorial Hospital. "It will be," says the appeal of the executive committee, "a provision for the relief of human suffering, from the cup of which he drank the bitterest dregs, and in the breadth of its human charity it will fitly typify the noble nature and exalted aims of the hero and martyr. The hospital is designed to be as wide in its scope of beneficence as was the kindly heart of the dead President in its outstretch of human sympathies. It will be open to those needing its aid and ministrations without regard to class, caste, creed, or color. To be a sufferer in need of help will be the only passport required to enter its doors and secure its aid. Such an institution, founded in the cause of charity and bearing the name of 'Garfield,' appeals to the generosity of every one, and to every one the appeal is made." At the suggestion of the committee, indorsed by a representative pastor of each religious denomination in Washington, a request has been issued to all pastors to set apart Saturday and Sunday next, November 5th and 6th, or the nearest available days, for discourses and collections in all places of worship throughout the land in aid of the hospital fund. The Washington pastors, Protestant, Catholic, and Hebrew, have joined with the committee in this appeal, which, it is hoped, will meet with a generous response. That the contributions will be properly applied is evident from the composition of the executive committee. Gen. W. T. Sherman is chairman of the committee, and among the members are Secretary of State Blaine, ex-Secretary of the Treasury Windom, Gen. G. D. Swaim, A. S. Solomons, the Hon. Josiah Dent, Justice Arthur MacArthur, James Gilfillan, Treasurer of the United States, Dr. J. M. Toner, Dr. E. Smith Townsend, Dr. F. A. Ashford, Dr. S. C. Busey, Dr. J. Ford Thompson, Dr. W. G. Palmer, Henry A. Willard, John W. Thompson, James H. Saville, Lewis J. Davis, Reginald Fendall, E. Frank Riggs, W. G. Metzerot, and H. M. Hutchinson. Treasurer Gilfillan has consented to act as treasurer of the fund, and all contributions should be sent to him. Small gifts will be acceptable as well as large ones.

THE PHYSICAL INFERIORITY OF WOMAN.—In M. Delaunay's now much-quoted researches upon woman's place in nature, the following facts are given as showing her physical inferiority: Among birds and mammals, including man, the nutritive phenomena are more intense in the male than in the female. The blood is denser, contains more red globules and hæmoglobin, and fewer white globules and water. Man eats more than woman. Yet although she eats less, the woman is more of a *gourmande* and eats more frequently. Our city women feed like children. The respiratory phenomena are likewise more intense in the man than in the woman; for an equal height he has a greater pulmonary capacity and a larger thoracic index than the woman, and he also absorbs more oxygen, though his respirations are less frequent. The temperature is higher in man than in woman, and the pressure of the blood greater, though the pulse is less frequent. The pre-eminence of the male over the female is especially evident from the point of view of animal life. The skeleton of the female is lighter in proportion to the total weight of the body; the woman, in all the physical characteristics of her skeleton, is intermediate between the child and the male adult, according to Topinard. The woman is not so right-handed as the man; the pre-eminence of the right side over the left is less in the female. Externally, the male is always larger than the female. The woman is not so heavy as the man, although she would often appear larger on account of the development of the adipose system, which in her is greater than in man. "In all our Indo-European series," says Topinard, "the woman is more prognathous than the man."

According to M. Delaunay's own researches, the woman is more flat-footed and less arched than man—a sign of inferiority; hence, he maintains, the preference of women for high-heeled boots. The female voice is always sharper than that of the male. Both in wild and domesticated animals, the male has the muscular system more developed than the female. The movements are more precise in man than in woman. Among pianists of the two sexes, the mechanism reaches a much higher degree of perfection in the men. The cranium has a greater capacity in the male than in the female. Huschke estimates for Europeans the mean capacity of the cranium at 1,446 cubic centimetres in man and 1,226 in woman, or a difference of 220 centimetres in favor of man. The form of the cranium also differs according to sex; in woman, according to Broca, the cranium is less high and more elongated. The brain of the male is heavier than that of the female; according to Broca, the brain of man is to that of woman as 111 is to 100. Further, the frontal lobes, the seat of the highest intellectual faculties, are less developed in woman than in man. On the other hand, the occipital lobes, which especially preside over the life of sentiment, are more voluminous in the woman than the man. In its totality, according to Professor Wagner, the brain of the woman is always in a state more or less embryonic.

PREVENTION OF PLEUROPNEUMONIA BY INOCULATION.—A sharp discussion upon this subject recently occurred in the Académie de Médecine, Paris, between M. Bouley and M. Leblanc. The former gentleman argued very strongly for inoculation. He asserted that it had been most efficacious as tried in Australia, Holland, England, and France, and that it ought to be enforced by law in the latter country. M. Leblanc recited cases showing that inoculation of the pleuropneumonic virus does not always confer immunity upon cattle.

PET ANIMALS AND CONTAGIOUS DISEASES.—The fact that pet animals can carry contagion, and thus be the means of spreading fatal diseases, is not widely known nor duly appreciated. We have heard of authentic cases in which scarlet fever was communicated from one person to another by means

of a cat. Dr. Hewitt, of Lake Superior, relates a somewhat similar instance in which diphtheria was communicated by the same animal. He had noticed for several days that his pet cat was suffering from an enlargement of the glands of the neck; he also remarked the same in other cats. His cat found a resting-place in the wall behind the stove, and there died. The day the animal was removed, diphtheria, in its most violent form, broke out in his family, resulting in the death of two or three of his children, and the doctor himself barely escaping with his life. Up to this time the community was remarkably free from sickness of any kind. It was the start of a severe epidemic.

We refer to this subject in hopes that more facts bearing upon it may be communicated by our readers. These are at present scarce, but a little attention paid to the matter would, no doubt, secure much that would be of importance to comparative and to preventive medicine.—*Journal of Compar. Medicine.*

Treatment of Cirrhosis Vulgaris of the Liver (Interstitial hepatitis).—In a paper published in the *Annali Universali di Med. e Chir.*, of August, Dr. Rienzi states that during the past year he has seen several instances of cure or remarkable amelioration in cases of cirrhosis vulgaris. He therefore combats the opinion of Frerichs, Lebert, Thierfelder, Jaccoud, Kunzer, Bamberger, Surré, etc., who claim that cirrhosis of the liver is an absolutely incurable malady. In eight cases of common cirrhosis cited, one patient was cured; in four instances, there was more or less remarkable amelioration, while in three no benefit was derived from treatment. The author's conclusions are these: 1st, cirrhosis of the liver is not to be enumerated as heretofore among absolutely incurable maladies; 2d, in some cases the milk-cure ameliorates the condition of the patients, in others it may completely abolish the morbid phenomena.

The iodide of potassium advocated by Prof. Semmola, proved inefficient in the experience of Dr. Rienzi, according to whom this remedy is useless, and may prove harmful to these patients. He attributes the former's favorable results to the fact that the milk-cure was used at the same time. Karlsbad water, natural or artificial, produces a little amelioration, but has no further effect. The milk-treatment furnishes the best results, and is the only one which justifies the hope of curing a patient affected with cirrhosis.

Effects of Removing Mountain Forests.—Attention has long been given to devising means to limit the ravages of these torrents, which ruin the land, threaten estates, destroy roads, and sometimes even compromise the existence of villages. Walls have been built along the banks to protect them, or across the streams to allay the force of the waters. The most efficacious means, however, as yet discovered, has been to maintain the woods on the slopes of the mountain. The effect of cutting away the trees in promoting the formation of torrents has not been doubted by the inhabitants of mountainous regions, and is clearly set forth by M. Surrell, who says: "When we examine the tracts in the midst of which torrents of recent origin have been formed, we perceive that they have in all cases been despoiled of their trees and bushes. If, on the other hand, we examine hills whose sides have been recently stripped of wood, we observe that they are cut up by numerous torrents, which have evidently been formed very lately. Here is a remarkable double fact—wherever there are recent torrents there are no longer forests, and wherever the ground is cleared these torrents are formed; and the same eyes that see the woods fall on the declivity of a mountain, may see appear there immediately a multitude of torrents."

The disastrous consequences of removing the woods from the Alps began to attract attention in the last century, and have since been discussed in many publications and official reports. In 1853, the Prefect of the Department of the Lower Alps said, in a report to the Minister: "If prompt and energetic measures are not taken, it will be almost possible to designate the precise moment when the French Alps will become a desert. The period from 1851 to 1853 will produce a new diminution in the number of the population. In 1862 the Minister will remark a continuous and progressive reduction in the number of hectares devoted to agriculture; each year will aggravate the evil, and in a half-century France will count more ruins and one department less." The departments of the Upper and Lower Alps actually lost thirty thousand inhabitants, or one-ninth of their population, between 1851 and 1876. A law for recovering the mountains with wood, which had been prepared by M. Forçade de Roguet, Director-General of the Administration of the Forests, was adopted by the legislative bodies in 1860, and was put in operation shortly afterward.—M. J. Cleve, in *Popular Science Monthly* for October.

Portion of an Arrow-Shaft Imbedded in the Lung of a Steer.—Dr. Francis H. Atkins, A. A. Surgeon, U. S. Army, Fort Stanton, New Mexico, sends us the following: "While slaughtering a steer recently, the butcher at this post found imbedded in the lungs of the animal a portion of the wooden shaft of an arrow, about thirteen inches in length, and the iron head of the same. The arrow impaled both lungs at about the sixth ribs, having entered between two ribs. The point struck a rib opposite on its lower bevelled border, and, glancing, chipped the edge of the bone, the arrow-head bending considerably, and curving around the outer surface of the next rib posteriorly, where it rested.

"The external portion of the shaft had been broken off by frequent bendings against trees, etc., leaving a much-frayed end just within the closed wound of entrance, which was marked by a well-healed cicatrix on the soft tissues about the ribs. The lung-tissues were in perfect health, and there were no pleuritic adhesions, while the arrow-shaft and head was apparently perfectly encysted. The sinew once uniting the head to the shaft had been absorbed. The shaft seemed encrusted at points with dried pus. The animal was about three years old, and, it seems probable, was above one year old when shot, else the iron point would have penetrated the rib, instead of bending and glancing. The butcher thought the steer was not as well nourished as it should have been. The arrow was doubtless shot into the animal by an Apache Indian, the ruthless slaughter of cattle being a favorite pastime of many Indians.

"The shaft-head and section of the chipped rib have been sent to the Army Medical Museum, Washington, D. C."

Concerning Sea-Sickness and Local Anæsthesia.—Dr. F. D. Lente, Pilatka, Fla., writes: "Will you permit me to insert a brief notice of two of your paragraphs collected from your exchanges, on page 389 of your last issue, for the benefit of your readers? In one, Dr. Hopkins gives a remedy for sea-sickness which relieved *him* on a short voyage,

and which he, therefore, recommends enthusiastically to the profession, under the head of 'Ergot for Sea-Sickness.' But, as he mixes equal parts of sodii bromid. with the ergot, there appears to be no reason why he should not head his article Bromide for Sea-Sickness. As the bromides are now the accepted remedies for the *prevention* as well as the cure of this malady, and as ergot has no such reputation, but usually disagrees with a weak stomach, I would suggest that it be left out of the prescription, the dose of the bromide to be much increased, and to be taken for three days prior to sailing (see 'Beard on Sea-Sickness'), as was originally recommended by me many years ago. An ounce of *prevention* is certainly, in this disease, worth at least a pound of *cure*.

"Article second relates to 'A New Method of producing Local Anæsthesia.' It states that 'Mr. Thomas Taylor, of the Agricultural Department at Washington, has devised a new freezing microtome, and, upon the same principle, a new method of applying a freezing mixture to the skin for producing local anesthesia.' In commenting on this ingenious contrivance, the *Cincinnati Lancet and Observer* says: 'It seems that ether-spray has had its days of usefulness.' If any of your readers should wish to revive the practice of local anæsthesia so much talked of and practised a few years ago, it may save them the expense of purchasing an unnecessary apparatus by reminding them that Arnott's old mixture of *ice and salt*, if properly applied, with no other contrivance than a piece of netting or tarlatan, will freeze the skin and cellular tissue white in a very few minutes, when an operation may be proceeded with for fifteen or twenty minutes with neither pain nor hemorrhage. You have simply to pound up the ice finely and mix it with fine salt, and apply in sufficient bulk.

Venesection vs. Providence.—A correspondent sends us the following extract from the valedictory address of Dr. R. B. Haywood, retiring President of the North Carolina Medical Society (vide *North Carolina Medical Journal*, July, 1881, page 1), and asks: "Is Dr. Haywood perfectly sure as to the time and place where this remarkable colloquy occurred? and will he kindly favor us with the original French in which (presumably) Messrs. Velpeau and Gerdy gave expression to this stunning witticism:

"I once had the good fortune of witnessing a consultation between Velpeau and Gerdy, in the *Hôpital la Charité*, Paris, over a patient with pneumonia. Gerdy proposed to bleed him. 'Bleed him,' says Velpeau, 'bleed him! What do I want to bleed him for? Don't kill your patient; but give God A'mighty a chance! 'Well,' says Gerdy, 'I am willing that God A'mighty should have a *reasonable* chance, but I don't think it will do always to give him *too much rope*.'"

Dr. John Menninger died on October 28th, at his residence in this city. He was fifty-seven years old, and in the active practice of his profession. Dr. Menninger came over from Germany as a political refugee in 1850. He had been a wealthy man, but his estates were confiscated. Since being in this country he took but little share in politics. Through all his life he was a close student, being particularly interested in chemistry. He made many important discoveries. Tinned paper was his invention, and brought him much money. He was a member of the German Social Scientific Society. Death was caused by a polypus growth in the throat.

The Woman's National Hospital.—The breaking of ground for the foundation of the Woman's National Hospital, at Wilton, Conn., was celebrated recently with appropriate ceremonies. Several hundred farmers, with oxen and plows, assembled, and after short addresses by the Rev. Mr. Thompson, of Wilton, and Dr. T. D. Crothers, of Hartford, and a poem by the Rev. Mr. Davenport, of Waterbury, Conn., a little daughter and son of the founder filled a barrow with the first dirt and wheeled it away. The oldest man in the town, Mr. John Jones, over ninety years of age, held the plow that turned the first furrow, amid great applause.

Virchow has just been elected to the Reichstag. He polled 17,400 votes, against 11,200 for the Rev. Dr. Stoecker, court preacher and leader of the anti-Semitic movement.

Quinine Insanity before the Courts.—Sergeant Mason, the guard who attempted the life of the assassin of President Garfield, will, it is claimed, urge the mental condition produced by the excessive use of quinine, as a defence of his act. Quinine, as has been shown by Kiernan (*Journal of Nervous and Mental Diseases*, July, 1881), may exceptionally produce insanity, but it can do so but rarely and only in persons strongly predisposed to insanity. A defence based on the plea of insanity from this cause should, therefore, be sifted with great care.—*Chicago Medical Review.*

Hydrophobia among the Dogs in New York.—For the first time since the establishment of the dog pound in this city, a case of hydrophobia has been found. It occurred in a half-Spitz dog, which was found on the streets, September 22d. The case was diagnosed at once by Dr. Ennery, veterinary surgeon. As stated by him, the dog showed very marked evidences of the disease. The animal was put in the dog cart, where he crept about slowly on his belly. The moment his nose touched anything, he would give a convulsive snap. He was evidently stone blind, and his eyes were deeply congested. The other dogs, as is usually the case, seemed afraid of him, and tried to keep out of his way, but he bit many of them before reaching the pound. The diseased animal was shot at once, and those bitten were drowned.

There is a prevalent error regarding the frequency of hydrophobia. This is the first case that has been found among forty-seven thousand dogs that have been drowned at the dog pound in the past five years.—*Journal of Compar. Medicine.*

Census of Medical Practitioners in this Country.—In the annual report for 1879 of the Commissioner of Education, Gen. John Eaton, just published, the following statistics are given:

"According to the census of 1870 there were, nine years ago, 62,383 physicians and surgeons in the country. The number of graduates reported to this office since 1873 is as follows: 1873, 2,391; 1874, 2,343; 1875, 2,391; 1876, 2,629; 1877, 2,911; 1878, 3,080; 1879, 3,271; or a total in the seven years named of 19,016. If to this number we add 2,000 for each of the years 1870, 1871, and 1872, a low estimate, we have 25,000 additions to the profession in ten years. This is much in excess of any proportionate increase in the population of the country and far beyond the loss by death in the profession. When we think of the numbers added without graduation, and even without preparation, the increase becomes appalling."

# Original Lectures.

## THE SLOW PULSE AND DISTURBANCES IN THE RHYTHM OF THE PULSE.*

By T. A. McBRIDE, M.D.,
NEW YORK.

A PULSE of 60 or less is usually pathological. Occasionally we meet with cases in which the pulse-beat in health is habitually below 60, but such examples are infrequent.

The following schema, taken from Dr. T. Lauder Brunton's book on the "Experimental Investigations of the Action of Medicines, Part I. Circulation," London, 1875, exhibits the causes of slow action of the heart as determined by experiment on animals, and if you will keep this before you, you will find that it will assist you in the explanation of many cases in which a slow pulse is observed:

A. Irritation of vagus roots: 1. Directly by the action of an excitant, drug, or pain. 2. Indirectly by increased blood-pressure. 3. Indirectly by increased $CO_2$ in blood. 4. Reflexly by irritation of some other nerve.

B. Irritation of vagus ends in the heart.

C. Increased excitability of vagus ends in the heart.

D. Weakness of the heart: 1. Paralysis of cardiac ganglia. 2. Paralysis of muscular fibres of the heart. 3. Degeneration of muscular fibres of the heart.

A slow pulse is a prominent or important symptom in the following pathological conditions:

1. *Fevers.*—In typhus, although the pulse, as a rule, ranges from 100 to 120, a slow pulse is not infrequently observed. Murchison reports cases in which the pulse was 28 to 40.† In such cases there is usually very great prostration, and the heart may be seriously affected by pathological changes which are common in this disease. In convalescence a slow pulse is very often present. It is well to bear in mind that in adynamic conditions the pulse-beat does not always correspond to every ventricular contraction. Often a pulse-beat at the wrist occurs only after two or three contractions of the ventricle have taken place.

In relapsing fever, although the frequency of the pulse is very great in the pyretic periods, yet in the intervals it is much diminished in rate.

"In the first half of the apyretic stage, however, the pulse usually continues a little above the normal standard, but for some days before the relapse, when the temperature has regained its normal height, the pulse is in many cases irregularly slow—often not exceeding 40 to 50; but assuming the erect position will sometimes raise it from 50 to upward of 100. The slow pulse is not due to slowness in the contraction of the heart, but to a prolongation of the pause."‡

2. *Diseases of heart and lungs.*—In attacks of syncope the pulse may fall to 20, and even lower, and continue at this rate for some minutes. In the early stages of endo- and peri-carditis a pulse of diminished frequency is sometimes observed. In most congenital affections of the heart, and particularly in the *morbus cæruleus*, a slow pulse is present. In fatty degeneration of the heart and in stenosis of the aortic orifice, the diminution in the rate of pulse becomes a sign of some importance in diagnosis and prognosis. In aortic stenosis the pulse is seldom lower than 50, and is small and incompressible. In fatty degeneration or Quain's disease it may fall as low as 30, or even 20, and a pulse of 10, with continuance of life has been observed. The pulse is small, gaseous, easily compressible. A slow pulse, with epileptiform seizures, has also been observed in cases in which fibrinous masses were found affixed to the walls of the ventricular cavity after death (Ogle: "Transactions Pathological Society of London for 1863," p. 89). Permanent slow pulse has likewise been observed to follow attacks of diphtheria, and the explanation offered for this has been the frequent occurrence of fibrinous masses in the heart, which become attached to the walls of the heart. Charcot, however, has suggested that in such cases some lesion of the medulla or cervical cord may be present.

In pleurisy, with abundant effusion, after the crisis of croupous pneumonia, in the early stages of gangrene of the lung, a slow pulse is often encountered. In all diseases of the air-passages, or of the lungs in which carbonic acid poisoning occurs, the pulse at first is slow, by reason of irritation of the vagus roots by this poison, but later the pulse becomes very much increased in frequency, from paralysis of the vagus roots by the increase of the poison in the blood. In pulmonary tuberculosis a rather frequent pulse is the rule, but sometimes the pulse diminishes in frequency, and Traube* states that this is a sign of bad import.

3. *Affections of the nervous system.*—In the first stages of cerebral hemorrhage and cerebral compression a slow pulse is of frequent occurrence, and may also be present throughout the attack, but usually, and especially when death is imminent, the rapid pulse succeeds.

In what is usually termed the second stage of almost all of the varieties of meningitis, the pulse is apt to be slow. Niemeyer† and Traube assert that if in the course of any disease with head-symptoms, the pulse should suddenly fall from a high rate, as 110 or 120 to 50, 60, or 70, suspicion should at once be directed strongly to the occurrence of a meningitis. The diminished frequency is most marked in basal, and especially in basilar meningitis, in which latter affection it may be 40, or less. In fractures of the cervical vertebræ, a slow pulse is common. Mr. Hutchinson‡ reports a case of fracture of the fifth and sixth cervical vertebræ, in which a regular pulse of 48 was observed. According to Gurlt,§ the pulse may fall as low as 36, and even to 20. Fractures of the first dorsal vertebra seem to be accompanied for a time also by this slowness of the pulse. The rule is for this slow action of the heart to be transitory, and to be replaced by a very great increase in the frequency, and this occurrence has usually a bad significance. The slow pulse may, however, continue for some time. In a case of Rosenthal's the pulse oscillated between 48 and 56

§ E. Gurlt: Handbuch der Lehre von den Knochenbrüchen, p. 62. 1864.

for four weeks, and the patient, a child, aged fifteen, recovered. In certain cases of irritation of the cervical spinal cord by neoplasm, tumors, pachymeningitis, etc., a slow pulse has often been noted. Charcot * has observed three cases. In one the pulse was from 20 to 30. In such cases syncopal apoplectiform and epileptiform attacks frequently occur, and in the attacks the pulse may fall to 15 or 20. He also refers to a case in which there was a decided narrowing of the vertrebral canal near the occipital foramen, in which a slow pulse was observed. In melancholia a slow and feeble pulse is common. Spring † records a case with a pulse of 15. In migraine and hemicrania the pulse rate is low during attacks, as a rule. Lieving ‡ quotes Wollendorf as follows: "From the beginning and during the continuation of hemicrania the rate of cardiac pulsations is considerably lowered, the normal pulse-rate of from 72 to 76 to the minute, sinking to from 56 to 48 beats." Lieving also records cases of gastralgia, hysterical asthma, epilepsy with gastric aura, in which, during the attacks, the pulse would fall to 50 and lower; also cases of hiccough, in which the pulse-rate was so reduced as to be synchronous with the hiccough.

4. In the period of invasion of erysipelas, diphtheria, and some of the exanthemata; in scleroma neuratorum; in convalescence from gastro-intestinal catarrh; in scurvy; gout; in certain cases of malarial affection; in jaundice; in the attacks of lead colic; in ergotism; and lastly, in some cases of uræmic poisoning in the course of Bright's disease, a pulse of 50 and less is not infrequently observed.

*Rhythm.*—The disturbances of the rhythm of the pulse are those of intermission and irregularity.

*An intermittent pulse* is one in which a pause occurs between the pulsations, which is equal to the time occupied by one or more pulsations.

The intermittent pulse may be present in perfectly healthy persons, and may have always existed. Dr. B. W. Richardson has also shown that it may be produced in a man otherwise healthy, by grief, terror, anxiety, fatigue, pain, passion, adverse fortunes, etc. When it is the only peculiarity of the pulse it is not a sign of any great importance, although it is observed often in cerebral hemorrhage, and in cerebral compression from fractures of the skull, in tumors of the brain, in gout and syphilis. It is present often in dilatation and degeneration of the heart, but is then associated usually with an irregular pulse, especially if the patient moves about. The ventricle requires the stimulus of a greater quantity of blood before it will contract, and one, two, or three contractions of the auricle may occur before there is a pulse-beat. In this way, since varying quantities of blood are thrown into the arteries, irregularity of the pulse results.

*Irregularity of the pulse* is a much more important symptom by itself than the pulse with intermissions. The following are some of the diseases or conditions in which an irregular pulse is a sign of importance:

1. *Neurosal irregularity.*—The irregularity of the pulse, which is often very great, may be provoked by peripheral irritation, as dyspepsia, meteorism, worms, etc. It often occurs in hysteria and hypochondriasis, and in anæmia. With the irregularity there is often intermission of the pulse. In this form of irregularity—the neurosal—exertion, effort, or movements of the body of any kind, have but little effect upon the disturbed rhythm of the pulse. The irregularity and intermissions are not increased, and sometimes are even diminished. Irregularity and intermissions of the pulse, however, when dependent upon valvular disease and degeneration of the structure of the heart, are much augmented by the slightest movement. The exaggerated changes in the rhythm are accompanied by dyspnœa, palpitations, and often syncope.

2. *Irregularity of pulse in heart disease.*—In most diseases of the heart the occurrence of degeneration of the muscular substance is marked by the appearance of an irregular and intermittent pulse. There is a variety of valvular disease of the heart, however, in which the irregular pulse is quite constantly present, and without any degenerative change having occurred in the walls of the heart—mitral insufficiency. The irregular pulse is frequently present in cases of mitral insufficiency for years, and the pulse is called the "mitral pulse." Sometimes the irregularity of the pulse cannot be appreciated until the arm of the patient is elevated, and in this position the irregularity is readily noted.

3. *Syphilis.*—Fournier * has called attention to the fact that irregularity is of frequent occurrence in the secondary period of syphilis. It may be in these cases irregular to-day and regular to-morrow. It may be irregular in the morning and regular in the evening. It may be associated with the other phenomena of secondary syphilis, or it may occur without any other symptoms of the disease being present at that time.

4. Dr. B. W. Richardson † refers to two forms of irregularity of the pulse, which it is of importance to recognize: "Acute Irregularity in Time" and "Prolonged Irregularity in Time."

"Acute Irregularity in Time:" Each stroke is given in the correct order of succession, the one stroke to the other, but in series of five, ten, or other number of beats, differing in rate from other series. In cases of very feeble heart we often meet this condition; we meet it in anæmia, we meet it after loss of blood, and other states of depression.

"Prolonged Irregularity of Time:" This is a condition in which the pulse shall, during one minute, register, say 70, and if counted through a succeeding minute, 90 to 100 beats. This form of irregularity in relation of time is met with most distinctively in cases of acute cerebral diseases, especially in the hydrocephalus of children. In hydrocephalus, according to my experience, it is a fatal sign. I have never known an instance of recovery when, with other acute disease, this prolonged irregularity has been markedly present."

Our forefathers in medicine christened some of the pulses with disturbed rhythm, and I will mention the names of some of them as curiosities, although a few are worthy of remembrance.

a. *Pulsus deficiens, an intermittent pulse.*—Where one or more contractions of the heart are entirely wanting, and no pulsation can be felt in any of the arteries. Pulsus deficiens has also been applied to that pulse in which every beat seems as if it were the last.

* Lectures on Diseases of the Nervous System by G. M. Charcot, second series pp. 108–120; trans. by the New Sydenham Society. London, 1881.

† Symptomatologie ou Traité des Accidents Morbides, par A. Spring, tome 1er, p. 501. Paris, 1868–1872.

‡ E. Lieving: On Migraine and Sick Headache. London, 1873.

* Leçons sur la Syphilis, par A. Fournier, p. 894. Paris, 1873.

† Discourses on Practical Physic, by Dr. B. W. Richardson. London, 1871.

b. *Pulsus intermittens.*—An intermittent pulse, but only so because some contractions of the heart are too feeble to produce a pulsation at the periphery of the wrist.

c. *Pulsus intercurrens aut incidens.*—A pulse which feels as if between two equal and regularly following elevations a dissimilar one was interjected, or a pulse in which a superfluous pulsation seems to occur from time to time.

d. *Pulsus coturnisans.*—Two or more pulsations are compounded into forming a doubly or trebly compound pulse, as — ⏑ — ⏑, or — — — ⏑ ⏑, or ⏑ — — ⏑.

e. *Pulsus caprizans.*—One which seems to leap like a goat. An imperfect dilatation of an artery being succeeded by a stronger and fuller pulsation.

f. *Pulsus intricatus.*—One but little developed, and unequally slow.

g. *Pulsus myurus.*—A pulse that gradually becomes smaller and smaller, like a mouse's tail.

h. *Pulsus myurus reciprocus.*—A pulse which, after having become gradually smaller to a certain point, as gradually increases to its fullest size.

The pulses that I have enumerated thus far are curiosities in name and existence. They would be difficult to discover, and have no especial value in diagnosis. The pulses to which I now invite your attention have some value in diagnosis.

i. *Pulsus bigeminus, biferiens, aut bisiliens.*—Traube has called attention particularly to this form of pulse. It is characterized by two short beats, followed by a long pause. Each of the two beats corresponds to a heart contraction, in contradistinction to the dicrotonus pulse, in which a double beat corresponds to a single cardiac systole. Traube regards this pulse as one of bad import, and as indicating a fatal termination of the case.

j. *Pulsus alterans.*—A secondary form of the bigeminus. A weak pulsation follows a strong one, and the pause after the weak pulse-beat is longer than that preceding it. This is of bad import.

k. *Pulsus paradoxus.*—An apparently irregular pulse, which becomes smaller or entirely disappears on inspiration. This pulse is met with in excrescent mediastino-pericarditis, and is explained by traction of the sternum or ribs by bands or growths which compress the aorta. It may also occur in chronic pericarditis, and occasionally also in cases of stenosis of the respiratory tract. In these cases Bamberger explains the change in the pulse rhythm by the varying intra-thoracic pressure, and the amount of blood consequently in the vessels.

---

A Case of Recovery after Twelve Minutes' Immersion is reported by Mr. Charles Pope *(Lancet)*. One reason for the recovery is believed to lie in the fact that the man's chest was kept pressed by weights, and thus the water was kept out of his lungs.

Birth-Marks.—The following good story is told of a physician of Dayton, Ohio: The doctor was recently attending a case of labor in the family of one of his patrons, who, though a very excellent man, is a little slow in the payment of his medical bills. Immediately after the birth of the babe, the father nervously asked: "Doctor, is the baby marked?" "Yes," quietly replied the doctor; "it is marked 'C. O. D.'"

The bill for that baby was promptly settled.

## UTERINE CHLOASMA, IN CONTRAST WITH ADDISON'S DISEASE.

By WILLIAM PEPPER, M.D., LL.D.,

Provost, and Professor of Clinical Medicine, in the University of Pennsylvania.

(Reported by Dr. T. H. Cathcart, Clin. Asst.)

Gentlemen—I will call your attention to-day to an obscure case sent to us for diagnosis, a case which has been very perplexing, and which, I am sure, will be of great interest to you. The patient, Jennie C——, is forty-one years of age, of Scotch extraction, and married. Her family record is good, free from any syphilitic, tuberculous, cancerous, or other taint; and there is no history of any exposure to unusual hardships or anxieties. She has never had any children. She always enjoyed good health until the onset of the present illness, which began twenty-one years ago, or one year after marriage, and without any apparent cause. It commenced with a feeling of general weakness, pain in the back and abdomen, and a profuse muco-purulent discharge from the vagina. The weakness did not cause her to go to bed, but made her indisposed to perform any active household duties. There was decided loss of flesh. Ten years later, the symptoms still continuing, but subject to periods of improvement and relapse, she noticed, for the first time, an arched band of bronzed skin on the forehead, and shortly afterward patches of the same color appeared on the cheeks and abdomen. With the appearance of this discoloration there was no alteration in the other symptoms, for the pain in the back and the sense of weakness were still felt, and the loss of flesh had not been regained. During the last ten years her condition has gradually grown worse. The weakness and emaciation have slowly progressed, the discoloration of the skin has become more marked, and the pain in the back more intense. In addition to these, she has suffered during the last eight months from several attacks of palpitation of the heart, and has fainted a number of times without any apparent cause. The weakness complained of has been greater at some times than at others, and has presented remarkable fluctuations, but always with a tendency to become worse. The periods of weakness would come on without any evident cause, and would generally last three days.

The emaciation has been subject to no fluctuations, but has been steady and progressive. The appetite and digestion have been poor, the bowels occasionally loose, but not sufficient to produce the weakness and wasting.

Careful examination of the patient yesterday disclosed no disease whatever of the nervous system, nor any sign of any pulmonary lesion. The heart is healthy, the pulse moderate in frequency and strength. The lymphatic system presents nothing abnormal, and the liver and spleen are of natural size. The urine is acid in reaction, with a specific gravity of 1.017, and is free from either albumen, sugar, or any deposit. The uterus is enlarged, congested, and retroverted. Its cavity measures three inches in length. The left ovary is prolapsed, and lies behind the body of the uterus. The catamenia are regular, last three days, but are attended with pain. The blood, as drawn from her finger and examined by my assistant, is paler than usual, from diminution of its coloring matter; but an enumeration of the blood-corpuscles with a hemacytometer, shows one cubic millimetre of blood to contain 4,450,000 red cells, and 1 white cell to

224 red ones, which, you know, is about normal. The discoloration of the skin is quite evident. There is a bronzed arch on the forehead and patches of like color on the cheeks. The backs of the hands and forearms are also discolored. These patches, the patient says, vary in shade from day to day, and are separated, you see, from the naturally colored skin, by a distinct line of demarcation. There is no discoloration in the axillæ, nor around the nipples, nor at the flexures of the joints. Lastly, there is decided weakness and emaciation.

I have been especially particular in detailing these symptoms, gentlemen, because you will appreciate their value and importance when we endeavor to arrive at a diagnosis. The case is, as you no doubt perceive, an obscure one, and yet upon its correct diagnosis will, of course, depend the treatment to be pursued, and the amount of good that we can do our patient.

The discoloration of the skin is the sign that would first attract your attention, and this, in conjunction with the progressive weakness and emaciation, would immediately raise the query, Have we to deal with a case of Addison's disease? But you should be aware, gentlemen, that a like discoloration of the skin sometimes occurs in chronic disease of the liver, spleen, stomach, uterus, intestines, or peritoneum, due to long-continued irritation of the abdominal sympathetic centres. Hence, in a case such as the one before us, we should be careful to search for the existence of any local irritation of the abdominal organs, to study the progress of the disease, and to analyze most minutely the various symptoms present. Addison described the disease which now bears his name, as a progressive, idiopathic anæmia, accompanied by general languor and extreme debility (but without much loss of flesh), and by a bronze discoloration of the skin. The heart's action he stated to be remarkably feeble, the pulse weak, much shortness of breath to occur on the slightest exertion, and death to result from asthenia in the course of from one to several years. It is a disease essentially of the suprarenal capsules, bodies without any definitely known function. They become the seat of a chronic inflammation, are enlarged, and later undergo a cheesy degeneration, and their capsules thicken.

Lying in close contact to the semilunar ganglia and their nerve-prolongations, a constant irritation of these great centres is produced; and it is by reference to the long-continued irritation of their numerous and varied plexuses that the different symptoms, such as pigmentation of the skin, palpitation of the heart, dyspepsia, breathlessness upon exertion, etc., are to be explained. The cheesy mass may also act as a centre of infection, and occasionally tuberculosis may result.

Having given the symptoms of Addison's disease, let me again direct your attention to the case before us, so that we may compare the two, and see in what they agree and in what they differ. The bronzing in the patient here is not uniform or diffused, but is separated from the naturally colored skin by distinct lines of demarcation; it has not progressed, and there is no discoloration around the joints, umbilicus, genitals, or armpits. It is true that, in cases of discoloration of the skin due to chronic disease of the abdominal viscera, it is usually limited to the face and abdomen, and does not, as in this instance, occur on the hands. But this is not a constant rule. I have known almost universal bronzing of the skin to attend chronic peritonitis, without any disease of the suprarenal capsules; while, on the other hand, in the present case there are no purplish spots on the mucous membrane of the mouth, and no bronzing about the genitals or in the flexures of the joints. The latter points are of value as being unlike what are apt to occur in true Addison's disease.

The feeling of debility has not been so extreme as in the latter disease; the tendency to palpitation of the heart has been very slight; and the gastric disturbances have been very mild. Lastly, the patient has chronic endometritis with prolapse of an ovary, with which condition there is often associated such irritation of the abdominal sympathetic ganglia as to prove the source of weakness and debility.

Progressive, causeless, and irregular debility (not accompanied with marked loss of flesh) is the most prominent symptom of this peculiar disease of the suprarenal capsules. The prostration and loss of muscular power cannot be explained by any functional disturbance that a patient may present, nor will diligent inquiry find any special lesion as a cause of the constitutional change. It seems that in the case before us we can develop a debility not due to any organic disease except a chronic endometritis with prolapse of an ovary. Now, in some women, a slight uterine catarrh will produce marked debility and disturbance of health, whereas in others a more serious disease of the womb will cause no bad symptoms whatever. Again, we have the weakness in our patient, accompanied with emaciation, while in Addison's disease the latter is not at all commensurate with the former. In Addison's disease we usually have vomiting, dyspepsia, or other symptoms of a disordered condition of the stomach; but in this case, although there has been some irritability of the stomach, it has been very slight, and the uterine condition is sufficient to explain it. Palpitation of the heart, feeble pulse, and breathlessness upon exertion, have not been at all prominent in the present case, as they are in disease of the suprarenal capsules; and those attacks which have occurred the morbid state of the uterus could readily produce. I would ask especial attention to the analysis of the blood in this case. The state of this fluid differs greatly in different cases of Addison's disease. As will have been seen, Addison regarded the disease as essentially one of progressive anæmia; and so in some cases there is a very marked degree of anæmia, probably due to some deteriorating influence exerted by the focus of degenerating exudation and to the reflex disorders of digestion. But in other cases the force of the disease expends itself on the nervous connections of the suprarenal bodies, and the composition of the blood undergoes but little change. Hence it is evident, that no diagnostic importance can be attached to the absence of anæmia in the present case. Lastly, the course of Addison's disease extends over a period of from two to five years, while the woman before you has been ill twenty-one years.

The case, gentlemen, you perceive is not clearly defined, but lies, as I may say, on the border-line. I think, however, that from the careful analysis and differentiation of its history, symptoms, and progress which we have made, we are safe in considering it as one of uterine chloasma with debility, due to chronic endometritis and prolapse of an ovary.

The prognosis, therefore, is favorable, and the woman will be benefited by local treatment applied to the womb, for which purpose she will be placed under the care of my colleague, the Professor of Gynecology. In addition to this, careful attention must be paid to her diet and mode of life, and in-

ternally a course of ferruginous tonics must be directed. Among the best of these would be:

℞. Acid. phosphorici diluti,
Tr. ferri chloridi.....aa f. ʒ j.

M. Sig.—Twenty to forty drops in a wineglassful of water, through a glass tube, three times daily, after meals.

Or,

℞. Elix. ferri pyrophosphat., quiniæ et strychniæ .....f. ʒ ij.

Sig.—Teaspoonful after meals, in water.

Hence, you see the importance of a correct diagnosis in such cases.

In Addison's disease there is no direct line of treatment, as we have no means by which we can influence the morbid process in the suprarenal capsules, and our remedial measures are consequently only palliative. I will merely indicate the leading ones. They are as follows:

*First.*—Rest. Especially during the periods of intense weakness, which occur at irregular intervals through the course of the disease.

*Second.*—Regulation of the diet. Only nourishing and easily assimilated food, such as milk, soups, eggs, farinaceæ, and oysters, should be allowed.

*Third.*—Counter-irritation over the region of the suprarenal capsules by irritating liniments and dry cups; but, best of all, by the actual cautery.

*Fourth.*—Electricity—either the faradic or galvanic current may be used.

*Fifth.*—The use of alteratives. Minute doses of bichloride of mercury, iodide of potassium, nitrate of silver, and arsenic, have seemed to do good. Cod-liver oil, iron, extract of malt, and the hypophosphites, may be used to influence nutrition, but exert no influence over the morbid process proper.

*Sixth.*—All specifics are without value.

---

Tincture of Iodine and the Chloralated Tincture.—After Coindent had first employed the alcoholic tincture of iodine in goitre, many were the applications of this remedy, but to Bonelli credit is due for pointing out its indications. The tincture of iodine stands foremost in the list of immediate external coagulants and remedies provoking adhesive inflammation in closed cavities.

Injections of iodine may bring about a cure as well by first as by second intention. The former takes place when cure results from one injection, as in ascites, hydrocele, etc.; the second when several injections are necessary, as in hygroma, atheroma, and cold abscesses.

Carlo Pavesi, to further increase the therapeutical powers of the tincture of iodine, adds to it chloral, which dissolves in it without decomposition.

The resulting preparation has the property of being miscible with water without precipitating. The proportions of its ingredients are:

| | |
|---|---|
| Iodine (very pure) | parts 20 |
| Chloral hydrate | " 30 |
| Spirits of wine, strength 36 | " 140 |

The solution should be filtered, and kept in an emery polished bottle. The liquid is of pure golden hue, soluble in water, and has an odor and taste which indicate its ingredients.

The chloralated tincture of iodine, on account of its marked coagulating powers over albumen, is an excellent hæmostatic, and very useful in the treatment of large wounds as an antiseptic and hypnotic. —*Lo Spallanzani.*

## THE CAUSES OF FAILURE IN OBTAINING UNION IN OPERATION WOUNDS, AND ON THE METHODS BEST CALCULATED TO SECURE IT.

Being Remarks made in a Discussion of the Subject before the Section of Surgery of the International Medical Congress.

By the late Prof. WM. WARREN GREENE, M.D.,
Portland, Maine.

Mr. President and Gentlemen: In the discussion of this question of the healing of wounds, than which, in my opinion, none of greater importance has occupied the time of the Surgical Section, the great need is the expression of individual conclusions and opinions from those whose experience and observation has been sufficient to give their deductions weight.

There is no time, nor is there any need, in a presence like this, to argue those points that have been presented in the able papers just read.

In the first place, sir, I desire to be clearly understood as to my position with regard to "Antiseptic Surgery." It has come to pass, accidentally, no doubt, that if a surgeon does not accept, in all its details, the method of dressing of wounds known as "Lister's Method;" if he does not use the spray, and carbolic acid solution for the spray, and all the other elements in Professor Lister's dressing, he is counted as opposed to, or, at least, as not practising, antiseptic surgery. All through the discussions in this body during the past week no allusion, in my hearing, has been made to *antisepsis* in surgery except under the name of Listerism. And every member will bear me witness, that whenever the details of that method have been alluded to, *carbolic acid* and *the spray* have been almost the only elements spoken of, and the only ones emphasized.

Now, sir, I protest most emphatically against being placed in any such false position. It is very much like calling a man an allopathist simply because he is not a homœopathist. I believe no thoughtful surgeon to-day denies the value, the desirability of the most perfect antisepsis, and, better still, asepsis possible. But the question with us all is, how best to fulfil these conditions or attain to them with the greatest safety to our patients. I suppose we have all been trying to solve this question; each in his own way. During an active practice, which for fifteen years has been very distinctly surgical, I have gradually been led to the following conclusions:

*First.*—That wounds are more certain to heal by first intention if thoroughly excluded from the air; and that for such exclusion fine cotton-wool, absorbent or not, according to circumstances, is the best agent.

It is true that superficial wounds, like those for removal of cancer of the lip, or for closure of hare-lip, heal perfectly well, if nicely apposed, with no artificial dressing whatever. But nature teaches us a lesson in all these cases by immediately furnishing such a covering of blood and lymph, as when dried is perfectly air-proof. And I am sure that all important wounds, like those of amputations, excisions, the removal of large tumors, and similar operations,

do best when covered in from atmospheric contact. For such purpose the finest quality of cotton-wool is the best of any substance that I have found. It is light, elastic, and practically air-tight, for in a few minutes after it is applied to the closed wound it adheres to the surface by the drying sero-lymph that it absorbs.

Again, if you assume the *germ theory*, Professor Pasteur long ago proved that cotton-wool is a perfect filter for all germs or spores that may exist in the atmosphere.

*Second.*—That thorough drainage is an important element in the best dressing for healing by first intention.

It is true that if you, by accurate apposition of the flaps and the thorough exclusion of air, immediately put the deeper parts in the condition of a subcutaneous wound, the tissues will very often take care of serum, etc. And, as Mr. Keith has said, in speaking of peritoneal surgery, each case must be taken on its own merits. After perfect cleansing, and perfect control of hemorrhage, just so far as we secure accurate coaptation of the parts, so far we do away with the need of drainage. But where we must leave cavities, union is facilitated by proper drainage. I think this matter is being overdone, however, by many enthusiastic followers of Chassignac using tubes so large and retaining them *in situ* so long that they, acting as foreign bodies, hinder the simple processes of nature.

For this purpose I prefer hair-drains whenever applicable, as in small or superficial cavities, as after removal of tumors, excision of the mamma, and in amputations. I speak, of course, of *primary* drainage—for the removal of the bloody serum that flows directly after the wound is closed. After intra-peritoneal operations, when needed, I prefer glass or decalcified bone. Rubber-tubes I dislike for any purpose. True enough, they will often serve. So would almost anything. But they are too soft to withstand the compression from the dressings, and too frequently become clogged and seriously filthy.

*Third.*—That whatever be used for cleansing the parts during any important operation, whether by sponging or irrigation, and whether pure water or a solution of any medicinable substance be employed, it should be of the same temperature, or a little higher, than that of the body.

I was exceedingly interested in the statements of Professors Buchanan, Royet, and others, made, recently, as to the value of maintaining the normal temperature of the body during abdominal section for any purpose. I believe that in years gone by I have lost several patients from failure to do this. The importance of this point grows upon me constantly with reflection. I mean the importance of *more powerful measures* than the heat of topical applications. But every gentleman present, and there are several of my former colleagues who are familiar with my practice, will bear me witness that I have long recognized and applied the principle locally. I try to avoid all chilling the parts, and prefer the styptic influence of hot to that of cold applications.

*Fourth.*—That for the control of hemorrhage ligatures of some animal material, rendered as aseptic as possible, are best, and that they should be used so freely as to make the wound dry, so far as hemorrhage proper is concerned.

What the material for ligatures will be in the future is doubtful. I was surprised to hear Dr. Marcey's testimony in favor of the caribou's tendon, for last winter I tried to split up the tendon of our common deer (*Cervus Virginianus*) and failed to get such nice parallel division as he reported. But whether catgut or some other material properly prepared will be the ligature of the future, I am inclined to think it will be animal.

To the final dressing I have already referred in my first proposition.

As to Professor Lister's method, or what has come to be generally called Listerism, I have to say that the elements of the greatest possible cleanliness, the use of animal ligatures, thorough drainage, and protection from atmospheric contact, have my most hearty endorsement, and I have for a long time employed these agencies. And I believe that in estimating the value of the systems *as a whole, these several parts have been entirely under-estimated*, the spray and carbolic acid having taken the larger share of the credit.

I object to the spray, because I deem it wholly unnecessary. The parts involved, as well as the hands and instruments, can be kept completely moist with any antiseptic solution that may be employed.

It is not only, in my opinion, unnecessary, but its use, as practised by Professor Lister, involves not only at the time of operation, but in the often very early and frequent subsequent dressings, an amount of detail and finessing that is hardly practicable for a surgeon in a large private practice.

Again, I most positively object to carbolic acid. I have seen no evidence that an agent in solutions so powerful that in prolonged operations the surgeon's hands become stiff and numb for days, as has happened to myself, and to several gentlemen in this room, is a proper or safe one to apply to large exposed surfaces. On the contrary, I have seen much of carbolic acid poisoning; and I am very sure that the profession generally are not aware of the extent of this evil, especially in exciting disease of the kidneys. It has not been looked for.

So I was not surprised, as some of you were the other day, at Professor Keith's statement, that for four months past he had abandoned the use, not only of the spray, but of carbolic acid, relying, as he says he does now, upon simple cleanliness, care about hemorrhage, and thorough drainage.

Now, sir, in America the success of Professor Keith as an ovariotomist since he began to use Listerism—and no one denies the thoroughness of his application of it—has been the *capital illustration* made use of by those who look upon the "Lister method" as the only true antiseptic treatment or proper treatment. And his statements only show how careful we must be to keep such broad questions open; how long, and large, and discriminating observation is necessary before we can settle down upon fixed conclusions. What does he say? I read from the notes that I took of his slowly, modestly uttered words. "True," he says, "I did have eighty successive recoveries after ovariotomy." "But too many of those came near dying." "I found a large number of cases having high temperature—105°, 106°, 107° Fahrenheit—the evening following the operation, and many cases of renal disturbance. But while I had this remarkable succession of recoveries, that, *stopping there*, would be a wonderful statistical showing, *out of the next twenty-five I lost seven*; one of acute septicæmia, in spite of the most perfect antiseptic (Lister's) treatment; three others of kidney disease—one of hemorrhage—that were undoubtedly due to carbolic poisoning. For four months past I

have abandoned the so-called antiseptic plan, and I am getting better results; am having less trouble than when using it. I look upon perfect drainage in proper cases as indispensable." And neither you, Mr. President, nor you, gentlemen of the Surgical Section, will soon forget the significant silence for a few moments after these statements, before the Professor—realizing the importance of this testimony, knowing that he had been quoted the world over as a most devout disciple of Lister, and as a man whose every statement stood unchallenged for truth and honesty—finally said: "I have felt it my duty, gentlemen, to make these statements, *because they are true*," and sat down.

I am inclined to think that, at least in the atmosphere of large hospitals, especially old ones, and, indeed, *perhaps*, generally in private practice, it is best, though in private practice not absolutely necessary, to use some article in the water used for sponging or irrigation that is antiseptic and indeed germicidal. For some time I have used boracic acid, in saturated watery solution, for this purpose, and have been well pleased with it. For although we talk about pure water a great deal, it is very rare, unless it has been recently boiled and is much more likely to be the medium of access of bacteria to the wound than air-dust. Again, all this class of articles seem to have *some* quality which renders tissues less prone to inflammation. How? is the question. Whether as germ destroyers or by some inhibitory influence by chemical action, which latter I think more likely, I feel sure such quality exists. But carbolic acid, over which the profession has gone wild, is not a germicide. It does not destroy bacteria; it paralyzes or anæsthetizes them *while applied*. But let the fumes pass off, and they recover and become as lively as ever. But there are true germicides that in potent strength lack the unfortunate qualities of carbolic acid—alcohol, chlorinated soda, salicylic acid, boracic acid, permanganate of potash, ozone; these are familiar illustrations. Offensive or irritant qualities are no evidence of therapeutic power in a substance, nor is the lack of such quality evidence of inertness.

One thing, however, must be said for carbolic acid. It is a prophylactic against inflammation, and a useful remedy in certain painful inflammatory and ulcerative processes. But it is too energetic for application to raw surfaces.

As I said in the beginning, this is a time for the statement of facts within our knowledge and of individual opinions based thereupon. So, to conclude, let me say, that so far as the local management of wounds best calculated to secure union by first intention is concerned, I at present prefer the plan I have indicated, *keeping the whole question wide open for any new light in the future.*

I have not alluded to, but we must never forget, the all-important matters of the patient's surroundings, and of constitutional conditions and treatment.

*First.*—The greatest possible cleanliness in every respect from first to last.

*Second.*—The use of aseptic animal ligatures in sufficient numbers to control *all* hemorrhage.

*Third.*—Thorough drainage, used with discrimination as to different methods in different cases and as to time of retention of drain.

*Fourth.*—The maintenance of the normal temperature of the parts during the operation. For which purpose use warm water—better to have been boiled—with some such article in solution of germicidal strength, as chlorine, boracic acid, salicylic acid, etc.; although I do not consider this last recommendation absolutely essential, especially in private practice.

*Fifth.*—Accurate, firm apposition by a *sufficient number* of sutures of some non-irritating material, such as hair, perfectly waxed silk, or metallic thread.

*Sixth, and finally.*—The perfect covering of the parts with light compresses of pure cotton-wool supported by proper bandages. Where there is to be much oozing, absorbent cotton should be applied next to the surface to take up the contents of the drains. Otherwise, nice wadding is sufficient.

Before closing, I wish, while I cannot accept all the details of his method, to bear hearty witness to the good effects of Professor Lister's work upon modern surgery.

The attention of the profession has been called, as never before, to the practice of *cleanliness* and *care*—care about drainage, hemorrhage, etc. Especially has the beneficence of his teachings and example shown itself in large and old hospitals. The air is kept purer, everything is done more neatly and carefully in the way of dressing. All praise and honor for this. And if the learned Professor, who himself is to close this discussion, shall be able to show us the need, on the one hand, and the safety, on the other, of those elements in his system to which I have objected, no one will be more glad to be convinced of the truth than I.

## ONE MODE OF IMPROVING COW'S MILK FOR HUMAN FOOD.*

By E. F. BRUSH, M.D.,

FELLOW OF THE N. Y. ACADEMY OF MEDICINE, MEMBER OF THE WESTCHESTER COUNTY MEDICAL SOCIETY, ETC.

Milk must be considered as an artificial product, not designed by nature to be taken from the animal by any other means than suction by the mouth of their young; therefore, we are impelled to improve the animal by all possible means to sustain the unnatural production. Naturally the cow suckles her calf two or three months, when the flow of milk ceases, the animal again becomes pregnant, the energy that was directed to the mammary gland returns to the uterine, and when gestation is complete it returns to the mammary gland again. But, after generations of breeding for this special purpose, the cow has come to allow herself to be milked by human hands from the time she drops her young until within a few days, or, at most, a few weeks of her next occurring parturition. We know that the first milk-colostrum is an active cathartic, a fluid totally unfit for human food. It undergoes putrefaction very rapidly, and is in every sense a dangerous diet for any but the young of the animal producing it, and even by them it can be ingested in harmful quantities. I have called attention to the fact, in an essay read before the County Society, that this colostrum is mixed with milk in many of the large dairies, and there is no law existing to my knowledge forbidding it.

It is also known that, in a given time after the cow has calved, and while still giving milk, sexual heat returns, and if the animal does not become pregnant the condition returns every three or four weeks. During this period the milk is quite unlike that of

*Read before the Yonkers Medical Society, October 7, 1881.

other times, and dairymen have learned from experience that it is unfit for the making of butter or cheese. Mr. Willard, a practical cheese-maker, says of it in a recent agricultural report: "The milk of cows in heat does sometimes play queer pranks with cheese. You will remember that I suggested this to be the cause of the trouble in the three cheeses which we saw at Frazier's factory made from one vat of milk, which Mr. F. said could not be properly cooked. I have had it occur in my own dairy, when several cows were in heat at the same time, when the weather was hot and the animals were more than usually excited. In the worst cases I have attributed it not only to the milk of animals in heat, but aggravated by that of those which became sympathetically excited and exercised and feverish in consequence of the cows which were in heat. Milk at such times is feverish and akin to a mass of putridity, and not unfrequently a fetid or very offensive odor is emitted from the whey and curd if used for cheese-making. Such milk will no more produce solid curd than it would give health or nourishment to a calf when taken into its stomach. When made into cheese, there is a tendency to undue fermentation and rapid decomposition, and its character is precisely similar to cheese made with putrid rennet."

Men might go on indefinitely selling this variety of milk for the nourishment of infants, and never discover that it spoiled them, unless, like cheeses, they were to be sold for a certain price if they reached a given age. You will bear in mind, gentlemen, that this variety of milk is produced usually during the hottest part of the season, when infant mortality is greatest.

The mammary gland is not an excretory organ through which matter already existing in the blood is filtered, but it is really a growing plant, and milk is the result of its growth; or, in other words, a watery transformation of the gland itself. Therefore, the production of milk depends on the development of the gland. Now, as the gland commences its work naturally when the uterine organs have completed theirs, and *vice versa*, the inference is they cannot properly work together, and such is the fact. Milk taken from the cow during pregnancy cannot be wholesome. You never allow a mother to nurse her child if she becomes pregnant. The cow also refuses suck to her calf when pregnant. In dairies where the production of milk to be sold unmanufactured is the aim, one great cause of loss is the sometimes abortion of every cow in the herd, and this, by good authority in agricultural matters, comes from the too close milking of the animals during their pregnancy—*i.e.*, milking them as long as they give a pint of milk. The product, under these circumstances, cannot, by any possible reasoning, be considered healthy, and yet thousands of gallons of such milk is sold for human food.

Now, the aim and object of this paper is to point out a procedure by which all the above evils can be avoided. I do not claim any originality for my proposition; but I will say that heretofore the spaying of milk-cows has been proposed as a money-making scheme—not, as I propose it, a life-saving procedure. And I hope, when we come to understand this subject of cows' milk for human food, and, as medical men and guardians of the public health and occupying the position we ought, viz., proposers of laws regulating production, care, and sale of milk, the law shall be that no milk sold for human food shall be other than the product of healthy spayed cows.

As I have repeatedly observed, the laws now existing in this State relating to milk seem to have been framed almost entirely by corporations. I can detect nowhere the work of scientific health-guardians, and the simple fact that health authorities, as they exist now, confine their whole scientific energy to throwing away what they claim to be watered or skimmed milk indicates that the subject has been neglected. In studying up the subject of spaying cows, I find a Mr. Winn, an American farmer, was the first to practise the removing of the ovaries from milk-cows. He made just claims of the advantages following the operation; but no one else seems to have practised it in this country. It was next advocated by Levrat, a veterinary surgeon in France, who wrote a treatise on the subject, claiming that it increased the flow of milk one-third, caused the supply to be constant and unvarying in quality, exempted the animal from the accidents accompanying the period of heat and risks and accidents during gestation, and much more easily fattened after they became useless as milkers. Next Régère, also a French veterinary surgeon, gave the subject attention for some time, and arrived at nearly the same conclusions as Levrat; and at the present time the practice of removing ovaries from milk-cows seems to be confined chiefly to certain parts of France and Switzerland, and it is practised not with the view of improving the quality of milk as a food, but to increase the production of butter and cheese. Never since Mr. Winn's time, to my knowledge, has it been practised in this country. Some standard agricultural works allude to the subject, but none that I have found advocate it.

Of course, like every radical change, one can understand why it has not been more generally practised. Farmers, as a class, are the most conservative, and the operation involves considerable trouble, and would appear to involve considerable risk; but I have been unable to find a report of a single death following the operation. If it were generally observed, other good results than the improvement of milk would follow. The practice dairymen observe, in disposing of their old and useless cows, is to allow them to run dry, become pregnant, and then fatten them for the butchers; as has been observed, they will fatten more rapidly under these circumstances. Last fall I saw twenty such animals slaughtered, and I confess the meat did not bear a wholesome appearance. From the butcher I learned that these animals cannot be killed in the summer time, as the meat will not keep dry enough to be disposed of. Of course this operation would limit the supply of veal, and bobbed veal would become extinct. It would not interfere with the supply of milk cows, because it would be necessary only to have spayed cows for the supply of milk in large towns and cities, and it is a well-known fact that within thirty or forty miles of a good veal market, which large towns furnish, very few calves are raised, because milk is the consideration. Charles L. Flint, author of "Milk, Cows, and Dairy Farming," Secretary of the Massachusetts State Board of Agriculture, etc., says: "And in milk dairies still nearer large towns and cities they (the calves) are hurried off at one or two days, or at most a week old."

It is unnecessary to describe the operation, but an essay on the subject will be found in a treatise on "Milch Cows," by M. Francis Guenon, translated by N. P. Trist, late United States Consul at Havana. published by the Orange Judd Company. When our milk supply is derived from spayed cows, as it should

and will be, it will be possible to obtain milk from animals without performing the reproductive act. Of course, reasoning from the knowledge we now possess, a heifer spayed would not give a large quantity of milk, because a cow does not give her largest amount of milk until her sixth calf, and those who have advocated spaying have advised it to be delayed until this period; but it might be possible that, if the animal's reproductive organs were in a quiescent state, the improvement might go on for the six years just the same, or, in other words, the improvement in milch cows may not be due to utero-gestation, but may simply be that it requires six years of milking to develop the mammary glands. If this is correct (which experience only will prove), then I can see the cow of the future being spayed when a calf, just as a young bull is castrated to be fattened for the slaughter.

## THREE TWIN LABORS IN ONE DAY.

By G. H. BALLERAY, M.D.,
PATERSON, N. J.

The occurrence of three twin labors in one day in the practice of the same accoucheur is an event so rare as to be deserving of record, and as each of the cases presented certain features of interest, I hope that a short report of them may not prove uninteresting to the readers of this journal who are engaged in the practice of obstetrics.

Case I.—Was called, May 14, 1873, at 10 P.M., to see Mrs. M——, primapara, aged twenty-four. The patient was a very tall and moderately stout woman. The abdomen was enormously enlarged; the os uteri almost fully dilated; the presenting head in the pelvic cavity and in the first position (L. O. A.); pains recurring regularly, but not very severe. 12 M.—Os uteri fully dilated; membranes ruptured; pains somewhat increased in force.

May 15th, 3 A.M.—Pains of considerable severity have recurred regularly since midnight, but are now becoming less frequent, and seem to have less force. As there was no evident obstacle to delivery, the pelvis being roomy and well formed, and as the delay seemed to arise solely from the inefficiency of the uterine contractions, one drachm of Squibbs' fluid extract of ergot was given. 4 A.M.—No advance; pains not increased in force or frequency by the ergot; considerable caput succedaneum; vagina rather dry; pulse somewhat accelerated; lips dry; thirst considerable; patient getting discouraged. The straight forceps were applied (without an anæsthetic), and the patient delivered of a large, living male child. The child having been handed to the nurse, I placed my hand upon the abdomen of the mother and discovered that there was another fœtus in utero. Vaginal examination failed to find any presenting part. External examination revealed the presence of the head on the left side of the mother's abdomen. Pushing the breech upward with my right hand and the head downward with my left, I was gratified to find, on vaginal examination, that it (the head) was lying directly over the pelvic brim. Maintaining it there by supporting the breech with one hand on each side until the woman had had five or six pains, I again examined per vaginum, and found the head well engaged in the superior strait. I now ruptured the membranes, and the uterus contracting on the body of the child, forced the head rapidly through the superior strait into the pelvic cavity. Confidently expecting a speedy termination of the labor, I directed that preparations be made for the reception of the new-comer; but I was disappointed. As soon as the head reached the point in the pelvis at which the head of the first child became arrested it ceased to advance, notwithstanding that the pains were quite strong and expulsive in character. After waiting an hour, and finding that there was no progress made, I gave a dose of Squibbs' extract of ergot to forestall hemorrhage, applied the straight forceps, and extracted another healthy, living male child. The uterus was made to follow the child by pressure exerted upon the fundus by the nurse during the extraction. The womb being well contracted, I passed two fingers into the vagina, and finding one of the placentæ there, I removed it. The other was protruding through the os uteri, and was easily removed by hooking a finger into its edge and extracting it.

After the patient had been bandaged and made comfortable, I remained an hour with her, fearing that post-partum hemorrhage might occur from relaxation of the uterus. At the end of that time, however, as there had been no hemorrhage, and the pulse was good, I was about to leave, when, on going back into the room to feel her pulse, I found it very frequent and feeble, and on turning the bedclothes aside I found a pool of blood in the bed, and saw that it was coming in a stream from the vulva. Placing my left hand upon the uterus I found it relaxed, the fundus reaching midway between the umbilicus and ensiform cartilage. Quickly passing my right hand into the uterus, I emptied it of clots; and ice being at hand I introduced some into the cavity of the uterus and also applied some over the uterus externally, firm pressure being at the same time exerted upon the fundus and sides of the uterus by my left hand and both hands of the nurse. These measures controlled the bleeding, but as the patient was considerably exhausted, I remained with her an hour and a half longer, stimulating her and keeping up pressure upon the fundus uteri to prevent relaxation of the organ and further loss of blood. The patient rallied well, and convalescence was so rapid that she was up and about the house on the twelfth day. The children were enormously large for twins—the first child weighed ten pounds and three ounces, the second nine pounds and seven ounces.

Case II.—Was called, May 15, 1873, at 8.30 A.M., to see Mrs. L——, a primipara, aged twenty-five, who was supposed to be in labor, although only in the eighth month of pregnancy. I found the labor far advanced; os fully dilated; head in pelvic cavity; membranes bulging during a pain; perinæum not rigid. The woman's lower extremities were very œdematous and her face puffy. I ruptured the membranes, and in fifteen minutes the patient was delivered of a living male child, which had evidently reached the eighth month of intra-uterine life. As the breech and lower extremities were passing into the world, with my left hand upon the fundus uteri I recognized the presence of a second child within the uterus, and very imprudently informed the mother of the patient of the fact, in the patient's hearing. The patient gave vent to an exclamation of horror and added, "then I will die," and immediately went into a violent convulsion. The convulsion was not hysterical, but had all the characteristics of the puerperal-uræmic convulsion. After the convulsion passed off, the patient gradually returned to consciousness, or rather to a condition of semi-consciousness.

I then made a vaginal examination and found the head presenting in the fourth position (L. O. P.). About twenty minutes after the first convulsion, a second occurred, followed in twelve minutes by a third, without any return of consciousness in the interval between them. After the third convulsion I found the membranes ruptured, and the head rotated with the occiput in the hollow of the sacrum. I hastened to my office for chloroform and instruments, and meeting my friend Dr. Blundell on the way, requested him to come and give the chloroform for me, which he kindly did. I applied the straight forceps and delivered the woman of a living female child, of about the same size as its twin brother. The delivery was so easy as to necessitate but the slightest traction, which was exerted with the right hand only, the left being used to protect the perinæum, which entirely escaped injury. The afterbirths were found detached and were removed without difficulty, and the uterus contracted well. The patient had no convulsions for an hour and a half after delivery, but at the end of that time they returned with increased violence, and bid defiance to all the measures adopted for their control.

My services being imperatively demanded elsewhere, my friends Drs. Blundell and Amiraux took charge of the case for me, and all that science could suggest was done for the relief of the patient, but she sank, and died at 5 P.M. I had known this patient previous to her marriage, and believed her to be the subject of chronic Bright's disease, although I had never been called upon to treat her professionally. She had, in the most marked degree, that peculiar and characteristic appearance of countenance so frequently observed in those who are the victims of chronic renal disease. Although this patient had anasarca, and a specimen of the urine, withdrawn by the catheter previous to the application of the forceps, became perfectly solid on the application of heat and nitric acid, yet I believe that if it had not been for my imprudence in abruptly announcing the presence of a second child in utero, when the patient was mentally congratulating herself upon the termination of her sufferings, she might not have had convulsions.

This is the second case in which I have known fright or mental shock to act as an exciting cause of puerperal eclampsia. In the other case, the woman, a primipara, had nearly reached the end of the ninth month of pregnancy, and had anasarca and albuminuria. She was suddenly informed of the death of a friend, who, singularly enough, had died of *puerperal convulsions*. She immediately began to tremble, and complained of feeling faint. She was helped to the sofa, and in a few minutes complained of pain in the head and flashes of light before the eyes. In less than twenty minutes from the time that the unfavorable news was communicated to her, she was seized with violent convulsions, which continued to recur, in spite of the most approved remedies (the patient being completely comatose between the paroxysms), until after delivery, which was affected by artificial dilatation of the os uteri and the application of forceps.

CASE III.—Was called, May 15, 1873, at 8 A.M., to see Mrs. W ——, aged thirty-six, the mother of three children. Patient had had labor pains for several hours, and was somewhat nervous and apprehensive of trouble, on account of the immense size of her abdomen. The os uteri was well dilated, the head in the pelvic cavity, and the membranes unbroken. I ruptured the membranes, and, in less than half an hour, the patient was delivered of a large, healthy female child. As the child was expelled, having my left hand upon the fundus of the uterus, I observed that it contained a second child, but I was careful not to communicate this information to the patient. Having handed the first child to the nurse, who went into an adjoining room to wash it (the husband of the patient superintending the operation), I made a vaginal examination, and felt a hand through the membranes. I oiled my hand and forearm, and having placed the patient on her back, with her knees drawn up, I gently introduced my hand into the uterus, seized a foot, and brought it outside the vulva. The uterus contracted well, and in a few minutes, the breech was expelled. I then hastened to deliver the shoulders and head. The child, a healthy female, cried vigorously as soon as it was born, and it would be difficult to describe the look of astonishment on the faces of the patient, her husband, and the nurse, as this entirely unexpected addition to the family thus boisterously announced its arrival. The patient afterward told me that she thought my manipulations had for their object the removal of the placenta.

The placentæ were detached by the uterine contractions, and easily removed.

The uterus contracted well, and the subsequent progress of the case was in every respect satisfactory.

## Progress of Medical Science.

THE TREATMENT OF CLUB-FOOT WITH APPARATUS.—Dr. James S. Green, of New York, contributes to the November number of the *New York Medical Journal and Obstetrical Review*, an article in which he argues that a great majority of the most intractable forms of club-foot may be treated successfully without the use of the knife. To effect the purpose of safe, comfortable, and certain reduction of chronic club-foot by mechanical means, he remarks, the instrument must perform the following functions: 1. It must effect by extension *the separation* of the articular surfaces of the bones involved exactly in the position in which they are presented by the deformity. The extension should be so complete that the synovial surfaces of the tarsal bones will slide *over* and *not upon* each other when the foot is twisted into its normal position. (This condition being obtained of itself reduces to a minimum the amount of force necessary to be exerted in moving the bones, which are thereby not jammed against each other, the synovial membrane and the cartilages injured, and ulceration of the soft parts made imminent.) 2. It should produce *the gradual* reduction of the foot to a normal position by continuous stretching, acting exactly in an opposite direction to the lines of the deformity.

In talipes equino-varus (the most common form) it should flex the foot, thereby overcoming the contraction of the gastrocnemius and soleus muscles, while at the same time it should abduct the foot, reducing the rigidity of the tibialis anticus and tibialis posticus muscles. It should stretch the plantar fascia, after overcoming the tendo Achillis and during the reduction of the tibial muscles. Withal, the instrument should be light in weight, portable, and easily worn, so that the patient may assist the cure by walking upon the foot which is being grad-

ually extended and drawn toward its normal position. It should be so constructed that, as the opposing tissues yield to the applied forces, the advantage gained, be it ever so little, can be easily seized and retained. The "compound club-foot twister," an instrument employed by the author and his associate, Dr. C. F. Stillman, is described as being so constructed as to twist the anterior portion of the foot on the posterior at the medio-tarsal joint, and also to gradually and painlessly alter the angle of the foot with the leg at the ankle joint. It consists of a local extender, provided with a slotted arc for graduated movement, placed each side of the ankle-joint, and another placed in front of the arch of the foot. Below, these are attached to a flexible felt or leather sole, on which the foot is firmly fastened by bandage; and above they are connected to metal terminal plates, which are bound down to the leg by some immobile dressing. This splint allows the foot to be twisted back into shape without pain, as it provides a local extension which relieves the parts from strain and attrition during the twisting, and also allows the patient to walk without interfering with the action of the instrument, the foot being completely under the control of the surgeon. The instrument and dressing used in a case related weighed thirteen ounces.

Conception without Introduction of the Penis.—Authentic cases of impregnation after contact of the male organ merely with external female genitals are so rare that the following history is of interest, if only in a medico-legal aspect. Sippel was called to assist in the delivery of a woman at full term, the husband stating that the genitals had completely grown together, so as to prevent the extrusion of the fœtus. On examination the head was found to protrude between the labia-majora during each pain, but was apparently entirely surrounded by a tense fleshy membrane, fully five millimetres in thickness. The waters had been very slowly evacuated; an opening, therefore, must necessarily have existed. After close search this aperture was found in the centre of the membrane, and having the size of a lead-pencil. A blunt-pointed bistoury was now introduced, and the fleshy diaphragm divided by a crucial incision, after which the delivery of a living child was easily effected.

On examination, fourteen days post-partum, the site of the hymen was found occupied by four tough fleshy folds, as thick as the little finger, while the vagina and uterus were normal. The condition of the parts in this case was such as to entirely preclude the possibility of the penis having entered the vagina, as, indeed, both husband and wife stated was the case. Not knowing any better, and conception having followed, they had believed that this was the usual method of sexual intercourse. No actual contact between the glans penis and cervix having occurred, it is evident that the spermatozoa must have penetrated from the vulva into the cavity of the uterus by their inherent active progression.—*Centralblatt für Gynaekologie*, April 30, 1881.

Echinococcus of the Mammary Gland.—To the eighteen previously recorded cases of this affection, E. Fischer adds one recently observed by him at the Strasburg clinic. At the age of seventeen the patient first noticed a hard, painless lump, as large as a chestnut, in the right breast. For three years the swelling remained pretty much of the same size, but then it began to grow anew, and gave rise to pains in the diseased part, which radiated into the right axilla, along the shoulder and down the arm. On examination, a tumor as large as an apple was found in the upper and outer part of the mamma about four to five centimetres beyond the nipple. On extirpation, the growth was observed to contain about fifty scolices, some of them grouped in clusters upon a common pedicle. At the same time a second tumor, of the size of a hazel-nut, was removed from the subcutaneous adipose tissue in the posterior axillary line of the left side. Its presence had been noted simultaneously with that of the first tumor. It had grown rapidly until it had attained the size of a pigeon's egg, after which the size had become reduced to its present dimensions. It was held to be an obsolescent echinococcus sac. The immigration of the parasites took place probably about two months before the tumors were first discovered, as at this period the patient had, on several occasions, suffered from gastric disturbances.—*Centralblatt für Chirurgie*, April 30, 1881.

Successful Removal by Tracheo-fissure of a Fibrosarcoma of the Lower Part of the Trachea.—After a short *résumé* of the history of endotracheal neoplasms, Meyer-Hüni relates in detail, in the *Correspondenzblatt für Schweizer Aerzte*, May 1, 1881, a case of the above description. The patient, a farmer aged twenty-seven years, suffered since boyhood from gradually increasing dyspnœa, which finally became so intense that suffocation seemed imminent. A laryngoscopic examination was made with the greatest difficulty. It sufficed, however, to demonstrate the presence of a tumor in the lower part of the trachea, growing from the posterior wall, with its superior extremity apparently on a level with the third or fourth cartilaginous ring. Expecting to be able to get at the tumor, and to remove it with the galvano-caustic wire, Meyer-Hüni performed tracheotomy above the isthmus of the thyroid gland, with partial division of the latter. But the growth was lower down than was anticipated, and, in fact, could not be seen from the incision. The patient being greatly exhausted, further operative interference was postponed until the following morning. At this time dyspnœa was very urgent. The cutaneous incision was prolonged downward for a distance of 1.5 centimetre on the manubrium sterni, the thyroid isthmus compressed between two suitable forceps, and divided between them. The tracheal incision was then extended downward as far as the episternal notch. On drawing apart the lateral halves of the trachea, the upper part of the tumor came in view; further examination showed it to be attached to the left side of the trachea by a broad base, which was then divided with curved scissors. The wound bled quite freely, but the hemorrhage was easily controlled for the time being by pressure with the finger. Afterward a Trendelenburg's tampon-canula was introduced.

On examination after removal, the tumor proved to be an alveolar fibrosarcoma, the dimensions being, 21 by 18 by 10 millimetres. The further progress of the case was marred by the development of a pleuritic effusion on the left side, and a mild broncho-pneumonia, besides several less threatening complications; but at the time of dismissal, three weeks after the operation, the tracheal incision was nearly closed by granulation, and the patient's general condition was excellent. On examining the interior of the trachea, a flat, but rather prominent mass of granulations was detected at the site of the original tumor. Whether this mass was composed simply of

granulation-tissue, or whether it was to be regarded as a recurrence of the disease, could not be decided at the time. Two months later the patient presented himself for examination. Respiration was then quite easy, and the voice was clear and strong. There was still some swelling of the mucous membrane of the upper portion of the trachea, preventing any insight into the deeper portions of the canal, but in other respects the patient seemed perfectly well and healthy.

Operative Fixation of Movable Kidneys.—Hahn has devised a new operation as a substitute for nephrectomy, in cases where this would be indicated simply by reason of excessive mobility of the kidney. The operation, which has been performed on two patients, may be briefly described as follows: The patient having been placed on the side opposite to that of the affected organ, an incision was carried along the outer border of the corresponding sacrolumbalis muscle from the lower border of the twelfth rib to the crest of the ilium, successively dividing the skin, the latissimus dorsi and the external layer of fascia enveloping the sacrolumbalis. The last-named was then drawn toward the median line, after which the quadratus lumborum muscle, and the fibrous layer of the peritoneum were incised. It may be remembered here that, according to Arnold, the kidney is not entirely extraperitoneal, the anterior surface of the viscus being covered by the serous layer, and the posterior surface by the fibrous layer of the peritoneum, so that an incision through the latter does not necessarily involve an opening into the peritoneal cavity. Pressure was now exerted upon the anterior surface of the belly, so as to force the kidney into the wound, to which it was there attached by eight or ten catgut sutures, after which the whole wound was plugged with carbolized gauze. There being no reaction, the first dressing was only removed on the fifth day, the subsequent ones at corresponding intervals. In about four weeks the wounds were almost entirely healed, and the kidneys were found firmly fixed in their new location. In both cases, however, a slight degree of mobility could still be detected at a somewhat later period. It would seem advisable, therefore, in future operations to partially strip off the adipose capsule from the posterior surface of the kidney and then to stitch this part of the capsule into the wound; it would also be preferable to fix the kidney as low down as possible, in order to give the organ a firm support, and to prevent any tension upon the seat of fixation during the assumption of the upright posture. Experience teaches that a dislocated kidney creates no disturbance, no matter how low it is placed, so long as it is firmly secured in its new location.—*Centralblatt für Chirurgie*, July 23, 1881.

Treatment of Hydrocele by Injections of Chloride of Zinc.—Impressed by the favorable results obtained in the treatment of sebaceous cysts with injections of chloride of zinc, Borck employed this procedure in a case of hydrocele of the spermatic cord, which he had previously tapped several times without permanent benefit. A few drops of a five per cent. solution were injected by means of a hypodermic syringe. This caused slight smarting, which lasted but a few minutes. The patient was kept in bed during the succeeding twenty-four hours. For a few days there was moderate sensitiveness on pressure over the hydrocele, but both swelling and pain rapidly subsided, and by the twelfth day the tumor had entirely disappeared, leaving only a slight thickening of the spermatic cord at the side of the injection. Even of this no trace was left after the lapse of about five weeks. Should this method of treatment continue to yield good results in similar cases, Sanger believes that it might be cautiously tried in cases where there is a communication between the sac and the abdominal cavity, perhaps also in desperate cases of ovarian cysts, where a radical operation is, for one reason or another, not permissible.—*Centralblatt für Chirurgie*, July 23, 1881.

Influence of Malarial Infection on Pregnancy, Parturition, and Childbed.—Goth claims that pregnant women are affected by malaria in the same ratio as other individuals. The malarial poison tends strongly to induce abortion or premature labor, the danger being the greater the farther pregnancy is advanced. This accident occurred in 41.3 per cent. of the cases under Goth's charge in the Klausenburg and Maternity. Some differences are noticeable, according as the fœtuses are stillborn or living. In the former event the uterine contractions are brought on by the presence of the fœtus acting as a foreign body, there being three factors which contribute to destroy its vitality—elevation of the mother's temperature, especially when it attains a height of 41.5° C. or more, long-continued anæmia of the mother, and the immediate toxic influence of the malarial poison. When a living child has been born, the premature uterine contractions have been incited by the febrile paroxysms. Such infants are usually much below the normal weight, four hundred grammes or more, and their viability is quite precarious during the first few months after birth. As regards the parturient act, Goth finds that the first stage lasts almost twice as long in women suffering from malaria as it does in ordinary cases. The typical course of intermittents is not interrupted, during or by parturition, except in so far as the paroxysms sometimes tend to occur at shorter intervals. During the puerperal weeks women are particularly liable to contract malaria. Whether this predisposition is due to the raw state of the genital tract, or to the general condition of weakness present cannot as yet be decided. The paroxysms at this time are often atypical, that is, the first or the third stage, or both, may be absent. In mild cases mothers may nurse, but in severe attacks the infants should be weaned. Quinine is fully as efficacious as in ordinary cases of malaria, and exerts no injurious influence on the nursling.—*Schmidt's Jahrbücher*, July 26, 1881.

Puerperal Infection in the Male—During the prevalence of a severe epidemic of puerperal fever in Pollenza a woman in childbed was attacked by a fever occurring in paroxysms and resembling intermittent fever. A few days after the last paroxysm, when the patient felt perfectly well, her husband attempted to have sexual intercourse with her, but the onset of intense pain in the region of the frenulum compelled him shortly to desist. He stated that he was sure something must have been torn at the time, but he had not noticed any bleeding. In a short while the pain subsided. Twenty-four hours later, however, a chill occurred, followed by intense fever, with remission of all the symptoms on the following morning. In the evening the chill and fever recurred. On the third day, the right inguinal glands became swollen. When called in to see the patient on the fourth day, Lapponi diagnosed ery-

sipelas of the skin of the penis, lymphangitis, and lymphadenitis. The erysipelatous inflammation continued to spread, the skin becoming gangrenous at several points. On the sixth day the patient died, with well-marked symptoms of septicæmia. Although not able to discover any laceration at the time of the first examination, Lapponi still assumes that the point of infection was a slight tear of the frenulum, which the patient suffered during the unsuccessful attempt at coition. — *Centralblatt für Gynaekologie*, August 6, 1881.

Capacity of Hearing in Children.—Weil states that too much attention cannot be directed to the fact that children attending school are often regarded as inattentive, when in reality they are more or less deaf. An examination of four thousand five hundred children in Stuttgart and its environs led to the following results: 1, A normal ear hears a whisper of medium intensity at a distance of twenty to twenty-five metres, when the surroundings are quiet; 2, disturbances of hearing are uncommonly prevalent among the young—in the public schools as many as thirty per cent. of the scholars hear quite poorly with one or both ears, while a still larger percentage do not hear perfectly; 3, among the poor we encounter defective audition more frequently than among the better classes; 4, the percentage of disturbances of hearing increases with age; 5, in country schools the conditions are comparatively better. Many of the affected children were not at all aware of their infirmity. Weil suggests that teachers be required to test the hearing of their pupils at the commencement of every school-year.—*Med. Correspondenzblatt*, August 13, 1881.

Nerve Suture.—Falkenheim believes that most of the recorded cases of primary union with rapid restoration of nervous function after coaptation and suture of the divided extremities of nerves are unreliable, because the reporters have neglected to take into consideration the existence of the so called supplementary mobility and motility, the *motilité et sensibilité supplées* of Létiévant. Most parts of the body are probably supplied with muscles which ordinarily act only as auxiliaries to other muscles, but which in the event of the latter becoming disabled, are fully capable of replacing their functions. A striking illustration of this is afforded by the muscles of respiration. The same is the case with sensory nerves. In a large number of rabbits, doves, dogs, and cats, Falkenheim divided either the sciatic or the pneumogastric nerve with a pair of sharp scissors, and reunited the divided extremities either with very fine catgut or silk sutures, using a fine lance-shaped needle, the cutting edge of which was passed in a direction parallel to the course of the nerve-fibres. The wounds, after cleansing, were closed with catgut sutures. In some of the experiments the nerves united directly, in others indirectly, in none was any inflammatory reaction observed. After the lapse of forty-eight hours the motility and sensibility of the operated limb were tested, and at the end of one or two weeks the nerve was exposed at the seat of operation and examined as to its functional capacity below and above the cicatrix. But in not a single instance was a restoration of conductivity observed.

In another series of experiments on young rabbits, the author divided, without subsequent suture, the tibial nerve, at a point where it lies firmly imbedded between the peroneal and saphenous nerves, and then exsected a small piece of each of the last two some distance beyond this. Here, also, the nerve stumps did not unite primarily, although the paralyzed muscles seemingly resumed their functions shortly after the operation. The apparent restitution of conductivity was due to the passive action of the extensor digitorum pedis communis. In the face of his own negative results, Falkenheim still believes that Gluck's observations warrant him in assuming the occasional immediate restoration of conductivity after division of a nerve. Reparation is, without doubt, hastened by suture of the divided ends. If accurate coaptation can be secured by introducing the stitches through the paraneurotic tissue, this procedure alone should be adopted. In case, however, the enveloping connective tissue has been extensively divided, or if considerable tension be present, the sutures may be passed directly through the nervous tissue, using very fine catgut as material, and passing the needle in such a way that its cutting edge shall lie parallel with the course of the nerve-fibres. If these precautions be followed, only insignificant symptoms of irritation, or none at all, will be developed.—*Centralblatt für Chirurgie*, August 20, 1881.

Hydrobromic Acid.—Massini regards this drug as a valuable acquisition to our stock of remedies. While the indications for its exhibition are the same as those for the other preparations of bromine, such as bromide of potassium, monobromide of camphor, etc., it possesses the advantage over the latter of having a more pleasant taste and of being better borne by weak and sensitive stomachs. The remedy was administered to thirty-one individuals with the following results: in four cases—one of violent neuralgia and sleeplessness, associated with cardiac disease, one of insomnia in an insane person, and two of aggravated hypochondriasis—it was of no value; moderate relief was afforded in seven cases—hypochondria with palpitation of the heart, hysteria with the same complication, nervous hyperemesis, hysteria with insomnia, the same with congestions at the menopause, hysteria with intense vertigo, and anæmia in a youth suffering from violent headache upon the least exertion. The acid was productive of marked and sometimes lasting benefit in the remaining twenty cases, comprising examples of nervous palpitation of the heart, insomnia, cerebral congestion and dizziness, paroxysmal headache in an individual affected with multiple sclerosis, congestive toothache occurring during pregnancy, persistent hyperemesis, hysteria, and, finally, pollutions from onanism. The remedy is best given about fifteen minutes after meals, in doses of ten drops of the concentrated (twenty-five per cent.) solution, or twenty to thirty drops of the dilute (ten per cent.) solution, well diluted with sweetened water. No unpleasant after-effects were observed.—*Correspondenzblatt für Schweizer Aerzte*, September 1, 1881.

---

A Case of Rupture of the Intestines, somewhat unique in character, is reported by Mr. William Walker in the *Lancet*. The patient, a young man of nineteen, had been drinking, and while in a stupid condition he fell off the shaft of a cart he was driving and the wheel passed over his abdomen. He showed no notable outward bruise, and was quite comfortable until the next afternoon, when he was taken with symptoms of peritonitis and soon died. The autopsy showed the duodenum to be cut entirely across.

# THE MEDICAL RECORD:

## A Weekly Journal of Medicine and Surgery.

New York, November 12, 1881.

## THE TREATMENT OF WOUNDS AFTER OPERATION.

In view of all that is being said concerning the so-called strictly antiseptic method of the treatment of wounds after operation, and the exceptionally good results claimed thereby, it would seem almost a work of supererogation to discuss the subject any further. But to any one who conscientiously studies the question of the healing of wounds and the best means to be employed to such an end, it becomes apparent that a considerable sifting of evidence is needed to reconcile the respective claims of apparently opposing doctrines and to reduce the same to the consistent level of generally accepted principles. There is a growing conviction in the minds of the large majority of surgeons that Listerism, so-called, is quite effectual in its way, but does not accomplish everything—in other words, that all the precautions usually insisted upon by enthusiastic advocates are not always essential to success. Hence it has come to pass that the spray is doomed to be banished from the operating theatre, that even now it is used only in exceptional cases, where extensive surfaces are to be exposed, and more in conformity with custom and its implied safety than for any demonstrably good results obtained thereby. A blind confidence in its good effects has made surgery bolder, has opened new fields for operation, and has thus indirectly added to the resources of our art. So far surgery owes much to the spray, but the more candidly an examination into its positive merits is made the more it is proven that this much-vaunted germ-killing vapor is the least important factor in the general summing up of cause and effect.

From time to time we have presented in these columns many proofs of this assumption, gathered from the experience of many who have studied the comparative effects of the different systems of wound treatment, and who have emphasized their statements by extensive observation and varied experience. Notably among these observers we refer to Kern, Guérin, Callender, and Bryant. To these names we could add those of many distinguished surgeons in this country. And the number is so constantly increasing that the spray is fast losing its charm, and the real safety of the patient is sought by other and better means against infection. What is said of the spray may be said of what are being claimed as some of the more essential elements of the Lister plan. Hence, while keeping the broad questions open, we are preparing ourselves for more fixed conclusions regarding the underlying principles of successful antisepsis.

In the discussion of the subject before the surgical sections of the International Medical Congress at its recent meeting in London, notwithstanding the admirable defence of the distinguished London surgeon, and the special pleadings of his enthusiastic followers, the strict antiseptic treatment, so-called, evidently lost ground.

One of the most practical contributions to this discussion was made by the late William Warren Greene, of Portland, Me., and we are afforded the opportunity of presenting his remarks in another column. This distinguished and experienced surgeon has, in a straightforward and telling manner, brought out many essential points in the successful healing of wounds, and has done very much to widen our views of antisepsis, pure and simple, and to establish many of those general principles upon which practical results must depend.

Dr. Greene very properly emphasizes the necessity of absolute cleanliness in wounds as the proper starting-point in rapid healing. The exclusion of air as a means to this end is not too strongly urged. In so doing we imitate nature in her efforts to seal wounds by glazing their surfaces with coagulated bloody serum, and afterward sealing them over by scabs. The giving them an opportunity for healing brings out another important element, that of rest. Perfect drainage is naturally dwelt upon as a prime necessity, but a very proper precaution is urged not to allow tubes to remain too long in a wound. We are convinced that many surgeons, in their anxiety to prevent the accumulation of pus in deep-seated wounds, really hinder their natural healing thereby. The employment of rubber tubes for the purpose is condemned, but the objections urged, although reasonably tenable, are not absolute. In recent wounds the hair-drains, used only until all bloody serum which may have escaped into the wound cavity is evacuated, are to be preferred. The absolute necessity of arresting all hemorrhage before the edges of the wound are brought in contact is forcibly presented, as a dry wound is a rapidly healing one. No surgeon has more effectually proved this than Mr. Keith, whose care in securing every bleeding point

is proverbial, and whose successes, even in ovariotomy, have claimed the admiration of his colleagues.

Animal ligatures are quite essential; but after perfect drainage and absolute rest, there is possibly no more important treatment of a wound than the proper stitching of its edges. Accurate approximation can always be maintained by the use of numerous sutures of fine thread. The material of the suture is of secondary importance compared with the conditions of their application. Ordinary waxed thread sutures of fine silk have, as is well known, remained in the soft tissues harmless for a fortnight and three weeks at a time, and sometimes have become perfectly encysted.

It is worth while to note that our contributor has wide and sensible views regarding the utility of the irrigation of wounds, and also has some definite convictions regarding the relative values of carbolic, boracic, and salicylic acids as disinfectants. Although many surgeons will not agree with him in his conclusions as to many of these points, there is a general testimony in favor of disinfecting every wound by some means or other, and preferably by carbolic acid, before applying any permanent dressing. When this is done thoroughly, it is safe to say that the spray is unnecessary. In fact, the latter is only advisable when thorough washing of the wound is impossible. Under such circumstances the spray is perhaps better than nothing.

In conclusion, and by way of summary, it is well to remark that the paper to which we have referred has helped the study of the question of antisepsis, by bringing out, in bold relief, the main principles which should govern the treatment of all wounds, viz., perfect coaptation, thorough drainage, scrupulous cleanliness, and absolute rest.

---

### THE INNOVATIONS IN THE PROGRAMME OF THE TRI-STATE MEDICAL SOCIETY.

The recent meeting of the Tri-State Medical Society, of which we give a report elsewhere, deserves some special attention from those interested in organizing medical work. It initiated two quite radical changes in its programme, viz.: it abolished its annual volume of proceedings, and it omitted all the municipal amenities and social relaxations customary upon such occasions. In the unadorned language of the committee, the members "were welcome to what they paid for, and no more."

The discontinuance of an annual volume is, we believe, a wise measure, and shows a progressive and practical spirit on the part of the society. We do not deny that there are advantages in having these publications as usually issued; but they are to be considered in the light of luxuries, not necessities, and are oftenest only the mausoleums of mediocre endeavor. When exclusive publication is required in these works, the result, as we have often enough said and proved, is unjust to author and injurious to the society. The action of the Tri-State Medical Society in this matter should be noted by other organizations, and the result of its experience appropriated.

The abandonment of all formal social enjoyments, of the historical banquet, the excursions, the speeches, the receptions, and of the musical pop of the champagne bottle, is a measure that will be more slowly adopted elsewhere. Many a hard-working man is attracted to societies in part by the pleasure of meeting friends and of interchanging views as well as greetings there. It may be that he learns more at lunch than in the session. As doctors work hard all the year, it is not surprising if they like some relaxation at their reunions. The examples of foreign societies show that good work is not incompatible with a railway excursion.

In fact, there are two sides to this matter, and it is a question which every society must decide according to the character and tastes of its members. The action of the society in question was satisfactory to its members, and it will no doubt be beneficial in general; for there has been and still is an abuse of this "relaxation" part of the annual work among a number of societies. But while rides on the river and the blandishments of lovely women should be made subordinate matters, it can be strongly argued that their complete effacement from the programme is not at all necessary.

---

### THE VALUE OF REPUTATION.

A striking instance of the value of reputation is given in a recent issue of *La Andalucia Medica*, in which it is stated that the autopsy of President Garfield was made by Doctor Longbranch. On general principles it would have been assumed that there were no better opportunities for becoming known in connection with the performance of professional work than were afforded by an association with the case of our lamented President. It may even be possible that our Spanish friends are in ignorance of the names of the gentlemen who signed the official bulletins. If our suspicions in this respect are well founded, it may be that none of the theories regarding the course of the ball are yet known to them, neither any of the surgeons who could have saved the patient had they been summoned to attend him.

---

### THE DANGERS IN THE AMERICAN SCHOOL SYSTEM.

Some undoubted progress in matters of school hygiene can now be recorded. The subject is being practically studied in Massachusetts, Wisconsin, Ohio, Maryland, and elsewhere. In some of those States the investigations are in the hands of boards of health; in other cases, work has been done only by local physicians under the direction of the school authorities.

It is in the Western States that some of the best

work has been done in this direction. The Wisconsin Board of Health has in particular published some excellent papers upon the subject. In its last report there is an article by Professor T. W. Chittenden, which enumerates very completely the ills that the growing boy or girl may be subjected to at school. Much as we have said heretofore about American schools and their attendant defects, it will not be inopportune to review again the list of them. It cannot be too strongly impressed upon the medical profession that the present methods of educating the young need a most thorough overhauling and revision.

The average school-child is liable to be subjected to a greater or lesser number of the following approved educational practices or incidentals of school management: a long enforcement of constrained or "military" attitudes, and the compelling girls, in particular, to stand for protracted periods of time; the prolonged sitting at desks, whose height or relation to the seat forces the child into a cramped position; a lack of supervision over the playgrounds; crowded rooms; dusty or impure air and poorly regulated temperature; insufficient or improper lighting of the rooms; lack of care to prevent the increase of myopia and of deafness. Few teachers understand that the "myopic eye is always a sick eye." Excessive studying out of school, irregularity in meals, insufficient recreation, the excitements and worry of examinations, the struggling for high marks, steady mental application without reference to changes in bodily functions or physical strength—all these unite to impair the health and often prematurely break down the constitution of growing children.

That these are not imaginary evils it is unnecessary to argue. Actual observation long ago established the facts.

We have recently received from Dr. L. B. Tuckerman, of Cleveland, O., the results of some investigations, which are somewhat novel in character, and which show some of the above-mentioned evils in a most striking light.

He writes that, during the last school year, of the eight hundred pupils in the Cleveland High School nearly twenty-five per cent. of the girls and eighteen per cent. of the boys withdrew from one cause or another. Investigations were authorized in consequence, and personal inquiries were made by a physician. It was found that seventy-five per cent. of the girls who had left had done so wholly or in part on account of ill-health. Of the boys, nearly fifty per cent. were in poorer health while in school, and thirty-three per cent. of those who left were compelled to do so on account of physical troubles. The Cleveland High School is about the same in character and requirements as other city high schools throughout the country.

Further inquiries were then made into the health of the scholars as well as of graduates. A very interesting fact was developed in regard to the relation of ill-health to the number of hours spent in study outside of school. It was shown, in the first place, that the girls studied, either from necessity or choice, more hours out of school than the boys did. We publish elsewhere, in full, a table showing that various symptoms of ill-health increased almost uniformly in proportion to the number of hours of outside study.

Another series of investigations showed that ill-health increased in inverse proportion to the amount of recreation or social enjoyment indulged in.

Altogether, the facts thus collected at Cleveland furnish very interesting and important data for educators to ponder over. The system of investigation adopted there is almost a new one. Its results, when more widely adopted, will be most valuable. Parents and school-trustees cannot gainsay figures like those of the Cleveland school, which show that the health of more than half the children drops below the level when attending school. Further investigations in this same line are being undertaken, and they cannot fail to lead to beneficial results.

---

### MISUSE OF ADVERTISEMENTS.

It is in the experience of every journal to be constantly solicited to call attention to advertisements and thereby directly and indirectly puff the wares of patrons of the advertising columns. If advertisers could really appreciate how little good can be accomplished by such means, they would not ask that it be done. The motive in so doing on the part of any journal is so apparent to the reader that he is more apt to become prejudiced against the article than otherwise inasmuch as it seems to be in need of vigorous puffing to make it sell. As is well known to our advertising patrons, we always decline to call attention, directly or indirectly, to any article in our advertising columns. We take it for granted that each article in the advertising department can speak for itself, and that our readers are sufficiently intelligent to form their own estimate as to the value of the testimony offered.

In view of these facts, we are somewhat surprised to see in the first issue of the *New England Medical Monthly* (October, 1881) an article taken from our advertising columns and quoted from The Medical Record as having appeared in our original department. The article is on page 28 of the *New England Medical Monthly*, vol. i., No. 1, and its publication under scientific abstracts is a barefaced deception upon the editor of that journal and upon its contributors and readers. It is, perhaps, unnecessary to say that no such article has ever been offered to The Medical Record, except as an advertisement, and could on no account appear in the body of our journal.

We make reference to this shortcoming on the part of the *New England Monthly* with the more regret, inasmuch as its first number is otherwise a model of its sort, and contains many highly interesting and practical articles. We believe the editor, Dr. Wile, has been imposed upon, and he should right himself at once with his readers and frankly state that the article referred to as having been quoted from THE RECORD was merely an advertisement, and could have appeared in THE RECORD in no other form. We would also respectfully call the attention of our exchanges to the matter, in order that they may not suppose by seeing the quotation that THE MEDICAL RECORD would be guilty of inflicting such an article upon its readers as a contribution to its scientific department, and that consequently they will abstain from giving it further publicity as such at the expense of our good name.

## Reports of Societies.

### SEVENTH ANNUAL MEETING OF THE TRI-STATE MEDICAL SOCIETY OF KENTUCKY, INDIANA, AND ILLINOIS.

*Held in St. Louis, October* 25, 26, *and* 27, 1881.

DR. A. M. OWENS, PRESIDENT, IN THE CHAIR.

THERE were about two hundred members present. Three sessions a day were held, and there were no excursions or banquets. The usual welcome address of the Mayor was also omitted, on account of lack of time. DR. H. C. FAIRBROTHER, on behalf of the Committee of Arrangements, said that these changes from the usual programme of medical society meetings had been made after careful consideration. The delegates were there for a special purpose, and no time should be wasted in complimentary speeches. They came asking and receiving no favors. They were welcome to that for which they paid, and no more.

DR. WILLIAM PORTER, on behalf of the Committee on Programme, spoke in the same vein. The usual banquet had been left out because it was not the purpose of the gentlemen assembled to spend their time in eating and drinking, but for the purpose of elevating and extending knowledge in the profession they had chosen.

The society then listened to the

ADDRESS OF THE PRESIDENT.

He spoke of the high aims and duties of the medical profession, and of the help and advantage which societies were in carrying these out. He referred to the Tri-State Society as an illustration, and briefly traced its history and growth. He then introduced the subject of the dangers to society from syphilis, and the method of preventing or lessening these. He offered no positive plan for such prevention, but made a number of suggestions, and finally asked that the subject be discussed by the society.

At a subsequent session there was a debate upon this address which was quite active, but which resulted in nothing worthy of note.

An excellent paper was read by DR. F. D. WASHBURNE, of Hillsboro, Ill., on "Medical Orthodoxy." The conclusion was that the only orthodoxy worthy of the acceptance of physicians is the broad-minded acceptance of the good, whatever its source.

A paper on "Pædiatric Practice" was read by DR. G. WHEELER JONES, of Danville, Ill.

On the second day a paper was read by DR. HEBAR ROBERTS, of Carbondale, Ill., on the "Use and Abuse of Splints in Fractures above the Elbow." An abuse which the reader enlarged upon, and considered dangerous, was that of making the splint too tight. This was done sometimes in deference to the opinion of the patient, rather than the judgment of the surgeon. In the discussion, the question of how much complete rest ought to be given the broken limb was raised. Some remarks on "Treatment of Fractures of the Radius by the Rubber Bandage" were made by DR. E. BROCK, of St. Louis; and quite an elaborate monograph on "The Treatment of Extrophy of the Bladder" was presented by DR. PRINCE, of Jacksonville, Ill.

DR. J. E. LINK, of Terre Haute, Ind., read an article on the "Reformation of Bone," in which he claimed to have been the first to have announced the possibility of such reformation after exsection. This he did for twenty years in Chicago, and his views were at that time ridiculed.

ABOLITION OF THE ANNUAL VOLUME OF TRANSACTIONS.

DR. DICKINSON, from the Committee on Publication, reported that the Committee's conviction was that the cost of publication of the proceedings in a separate volume would be too expensive, and, besides, such a volume would have too small a circulation. Therefore, they believed in conferring with the authors of the papers, and learning from them the medical journal in which they preferred to publish such papers.

After some discussion, a motion was made and carried, that the matter be left discretionary with the Committee, provided that the several authors of papers indicate, before going home, their preference, if they entertain any, in regard to the journal in which they would wish them published.

DR. B. M. GRIFFIN, of Springfield, Ill., read a paper entitled "Headache: Cause and Cure," which covered the subject very completely. He called special attention to headache from eye-strain. In the subsequent discussion, the efficiency of galvanism in treatment was referred to. In the intense headache of cerebral or cerebella disease, DR. HUGHES had found saturating the head with sulphuric ether very satisfactory.

DR. C. H. HUGHES, of St. Louis, read a paper on "Insanity in its Relation to Law." He criticised the present status of the laws regarding insanity, and spoke of the great injustice which legal ignorance had wrought. The chief aim of his paper, however, was to plead for statutory enactments

FORBIDDING MARRIAGE

among those likely to become insane, epileptic, etc.

"There are," he said, "methods humane, and they ought to be made lawful, by which insanity may be abridged, and the great horde of neuropaths that follow, like sick and wounded stragglers of an army, in the march of civilization; methods that would leave no stain of blood on the judiciary, no foul blot of murder on the State's escutcheon.

"The neuropathic diathesis, the insane constitution that breeds its like, and burdens the State with

hereditary imbecility, idiocy, insanity, deaf-mutism, and the lesser degrees of mental defect, must be made the subject of statutory enactment and enforced law. Sentimentality must yield to fact; the teachings of nature must be heeded and as sternly enforced as her own unerring edicts are. Why should the confirmed drunkard be permitted to beget a race of imbeciles, epileptics, idiots, or criminals? Why should the life-long criminal and pauper be allowed to go on reproducing his defective kind, the lunatic likewise, and all the mentally maimed of whatever degree, especially when by forfeiture of liberty they fall under proper custody of the law?"

The case of Guiteau was discussed, but no judgment pronounced, the speaker concluding with, "Time will tell."

REFLEX CONTRACTION OF CORPORA CAVERNOSA

was the title of a paper by Dr. J. T. Hodgen, of St. Louis. He stated that the cases described in it formed addenda to those described in a paper read by him before the Missouri State Medical Association in 1876. They presented peculiar features, which he had not recognized in any other reported cases.

Dr. Ford thought the cases described by Dr. Hodgen identical in symptoms with those mentioned by Van Buren. But Dr. Hodgen had excelled the latter in giving a correct rationale. He himself had a case of the kind in hand.

Dr. A. B. Bernays presented another case. He mentioned that he had sent the man to a specialist, who dosed him with iron, quinine, and strychnine, charged him $100, turned him loose, and did not cure him. Then Dr. Bernays performed a radical operation for varicocele, and his patient was cured.

Dr. A. G. Williams read a short paper on "Congenital Ptosis," with a report of a case.

The Secretary read a paper from Dr. E. Walker, of Evansville, Ind., detailing his success in several cases which he had treated with

STATIC ELECTRICITY.

Dr. Hughes spoke very favorably of this form of electrical treatment.

Dr. H. Wardner, Superintendent of the Insane Asylum at Anna, Ill., read a paper on the

CARE OF THE INSANE,

illustrating, by the cases of the burned asylums at Anna and St. Joseph, where it became necessary to erect temporary dwellings, that the cottage system, with out-door recreation and work, is best for the chronic insane, and that these annexes ought to form a part of the asylum. Of course there should be a main building for the more violent.

Dr. Hughes made remarks on the system, which, he said, was practicable as an annex system; but as to dispensing with a main building, that was impracticable.

Dr. Stephens said that no insane asylum should be built higher than three stories. It ought to be spread out on the ground, not upward in the air. He would condemn the St. Louis Asylum, for the reason that there was not room or opportunity for the patients to exercise themselves, especially in out-door work.

Dr. Hughes again spoke on the question. He said that every State asylum should have at least one hundred and sixty acres of land. Two hundred and fifty is the limit of numbers that should be allowed in one building, under the care of one man. A superintendent must be able to recognize each, to keep his family history in memory, and all the minor details. When he loses sight of the personnel of any, he has more under his care than he should have. The objection to the cottage system comes in during inclement weather, when the chapel, the lecture-room, exhibition hall, etc., cannot be visited. Then the patients become restless and dissatisfied.

Dr. Johnson did not believe in the "palaces" erected for the insane, and he did not believe in gathering all the insane of a State at one point. For the victims of insanity, consequent upon masturbation, he would recommend castration and dismissal.

The elder Dr. Prince referred to the asylums in France. There are four thousand patients in one institution, but they are divided into many departments, under special physicians. As the superintendent is merely business manager, things move well enough.

At the concluding session, the President was instructed to inform the Committee of Arrangements for the next annual meeting that the innovation which had met with such success at this meeting shall be carried out, and that no banqueting or other entertainment is desired, but that the meeting shall be strictly a business one.

The society then adjourned, to meet again at Terre Haute, Indiana, in September, 1882.

## NEW YORK SOCIETY OF GERMAN PHYSICIANS.

*Stated Meeting, April* 22, 1881.

Dr. E. Gruening, President, in the Chair.

PENETRATING WOUND OF SCLERA—SUTURE—RECOVERY WITH NEARLY PERFECT VISION.

Dr. Fridenberg exhibited a young man who had received a severe injury of his right eye. The accident had resulted from the bursting of a soda-water bottle. There was an angular laceration of the sclera. One portion of the wound started from the corneal border and proceeded directly backward in a horizontal plane. This cut was 1½ ctm. long. A second shorter wound was found joining the first at an angle, and passing upward. The upper lid was also wounded. Owing to the deep laceration, the vitreous had become exposed. After cleansing the eye with a concentrated solution of boracic acid, the wounds were closed by suitable sutures, atropia instilled into the eye, and a compression dressing of borated cotton applied. No reaction followed. The palpebral sutures were removed on the fourth day, and the scleral sutures came away on removing the dressing on the seventh day. Indiscretion on the part of the patient caused a temporary delay in the progress of the healing; but two weeks later the dressing was permanently removed, and the patient was now doing well. Vision was quite good, and still continues to improve. There was some symblepharon, and also slight hypermetropic astigmatism, the result of cicatricial contraction. The optic neuritis and opacity of the vitreous, still found on ophthalmoscopic examination, were likewise getting better.

Vision was now $\frac{20}{100}$, and, when corrected, $\frac{20}{50}$. Certainly the result was a very good one. Formerly such cases, as a rule, terminated unfavorably. The modern success of treatment was thought to be largely due to antiseptic precautions.

Dr. Gruening said that he had never seen a more

satisfactory result after deep wounds of the sclera than the present one. It should be remembered that the laceration in this instance was quite extensive, including, as it did, injury of the ciliary body.

According to former experiences, the prognosis of this case would have been unfavorable. He thought that, in addition to the antiseptic mode of treating the wound, the manner of applying the sutures, so as to include only the conjunctiva, had contributed toward a successful healing.

Dr. Welt alluded to a similar case observed at Knapp's clinic, where an equally good result was obtained under a simple dressing without any attempt at antiseptic precautions.

In reply to an observation questioning the antiseptic power of boracic acid, Dr. Gruening remarked that, according to the recent investigations of Schmidt-Rimpler, a concentrated solution of this acid was an almost absolute safeguard against septic infection. He would be unwilling to return to older methods of therapy after his uniformly favorable experience with the new plan.

For the past two years he had not seen a single case in which supervening suppuration had marred his results. The rule was healing by primary intention. And this circumstance should not be underrated in ocular surgery, where, as was well known, suppuration frequently terminated in the destruction of the eye.

### CIRSOID ANEURISM OF LOWER LIP.

Dr. Mravlag exhibited a young man, aged fourteen, who showed a cirsoid aneurism on his lower lip. About ten years ago the patient had sustained a fall, thereby injuring his lip. Inflammation had followed the accident, but no permanent damage had remained. Since ten months the same lip had gradually become tumefied, until at present the evidences of cirsoid aneurism were unmistakable. Therapeutical attempts had not hitherto been made.

Dr. Jacobi expressed the opinion that operative interference should not be resorted to in cases of this kind. The best results would probably follow the use of the thermo-cautery. It would be well, however, to apply only a moderate degree of heat, and this might bring about the obliteration even of larger and distinctly pulsating arteries.

### LARGE NASO-PHARYNGEAL POLYPUS IN A CHILD.

Dr. Wm. T. Kudlich presented a specimen, consisting of a large fibroid polypus removed from the lateral wall of the pharynx in a child aged four years. The growth had extended into the posterior nares, causing a putrid coryza, and leading to anæmia and severe constitutional disturbances on account of sleeplessness from dyspnœa. At first the neoplasm was mistaken for a hypertrophied tonsil. When its true nature became apparent, it was at once removed, and a speedy cure followed.

### URETHRAL POLYPI.

Dr. Klotz related the history of a patient from whose urethra he had removed several polypoid growths by means of his modified Grünfeld's polypotome. This case has already been published in full. (See Medical Record, August 6, 1881.)

### RECURRENT SYMMETRICAL HERPES ZOSTER.

Dr. Zinsser described a case of this kind which had recently come under his observation. The patient was a young man of about nineteen years of age. He had suffered occasional attacks of zoster for many years. Each attack was ushered in by constitutional disturbances, which the patient described as closely resembling sea-sickness. The intervals between the seizures were marked by apparent health, barring only a slight anæmia. No regularity was observed in the recurrence of the attacks. The bilateral symmetry, taken in conjunction with the recurrent nature of the eruption, certainly constituted the case one of great rarity. Neuralgic pains were never experienced by the patient, nor was his temperament or constitution of the neurotic type. The local pains incident to the appearance of the eruption had never been severe.

Kaposi had observed but a single case of this kind. Besides this, the same author mentioned only two similar observations by others. Dr. Zinsser thought the disease in this instance was probably of central origin.

Dr. Langmann said that he had witnessed meningitic irritation as an accompaniment of zoster involving the eyelids.

Dr. Jacobi gave a brief synopsis of the various theories advanced in explanation of the disease. He concluded by saying there could hardly be any doubt about the situation of the disturbance, which he located in the vaso-motor centre of the medulla oblongata.

### SPONTANEOUS AND SUDDEN ACCELERATION OF THE HEART'S ACTION.

Dr. Zinsser reported a case in which he had observed a peculiar and, to him, inexplicable cardiac symptom. The patient was a man, aged forty-four years, apparently in the enjoyment of full health, and not addicted to excessive indulgence of any kind. Suddenly, and without the slightest cause or premonition, the heart's action would leap from a normal rate to about 160 beats per minute. No untoward symptoms followed the paroxysm, and, apart from some sense of dyspnœa, none accompanied it. As a probable cause of such suddenly increased cardiac action, he had found in English descriptions of similar cases only the mention of worms and excitement. In the present case no cause of any kind could be made out.

### RUBEOLA AND MEASLES.

At the instigation of Dr. Scharlau, a prolonged discussion here ensued as to whether rubeola and measles were entirely distinct affections or merely different manifestations of the same disease. The general consensus of opinion was to the effect that they were separate maladies, having, however, some symptoms in common, which would often render the diagnosis of a given case a matter of some practical difficulty.

Before the society adjourned, Dr. Jacobi, in a few appropriate remarks, alluded to the recent death of two formerly very active members, the late Drs. Herzog and Goldmark. Suitable resolutions of condolence were passed.

---

*Stated Meeting, May* 27, 1881.

Dr. E. Gruening, President, in the Chair.

### SYPHILIS HEREDITARIA TARDA.

Dr. Klotz exhibited a male patient, aged fourteen years, subject to hereditary syphilis, with late development of symptoms. Large cutaneous surfaces were covered with ulcers and cicatrices, some of which apparently took their origin from the periosteum, others being confined to the skin.

According to Oganieur, the nerves and organs of special sense were commonly the first to be affected. In this instance no symptom pointing to such an occurrence could be discovered. Recently the idea had been generally abandoned that certain lesions of the teeth were characteristic of congenital syphilis. In this case also the teeth were not implicated.

The PRESIDENT remarked that in all the cases of parenchymatous keratitis which had come under his observation, the teeth had shown marked syphilitic lesions. In fact, this variety of keratitis appeared to occur almost exclusively in patients having congenital syphilis.

#### COMPLETE OCCLUSION OF LEFT SIDE OF NOSE.

DR. BRANDEIS showed a young girl who had come to him with a nasal obstruction of the left side. After removal of several polypi, he found a complete bony occlusion about one and three-fourths inch, from the nostril. Nasal breathing was entirely restored after perforation of the bony plate by means of the galvano-cautery.

Luschka had described only two such cases, and, according to him, the condition was commonly a congenital one.

#### PROBABLE CEREBRAL SYPHILIS.

DR. BRANDEIS also exhibited a young man, and gave the following history of his case. Some six years ago the patient had had a chancre. Vestiges of specific ulcerations and osseous hypertrophies were still visible. He had also suffered from various rheumatoid pains. About six months ago he had an epileptic seizure, and two similar attacks since then. At present he complained of vertigo and deafness. An examination revealed a bilateral otitis media and complete deafness. There was also a lack of power of co-ordination in walking.

DR. JACOBY had treated the patient with iodide of potassium, and a marked improvement had followed. He did not regard the case as one of the internal ear, but as an instance of cerebral syphilis, with a lesion at the rhomboid fossa, near the exit of the auditory nerve.

DR. SEESSEL observed that a lesion at the rhomboid fossa would of necessity implicate the pneumogastric, hypoglossal, and glosso-pharyngeal nerves. Symptoms pointing to a lesion of these nerves were, however, not found in the patient.

DR. RUDISCH stated that, according to Charcot, epileptic seizures had never been observed in the early stages of Ménière's disease. He believed the disease was situated in the pons varolii.

The PRESIDENT said that bilateral otitis media was not rare. Syphilitic lesions of the internal ear in such a case would account for all the symptoms observed in the present instance, without the supposition of a central nerve-lesion.

DR. ZINSSER replied that the occurrence of epilepsy in this patient militated against such a view of the case.

DR. SEESSEL presented some photographs of transverse sections of the spinal cord. He had obtained them through the kindness of Dr. Gray, of the Utica Asylum. They illustrated, in a very perfect manner, the typical spinal lesions found in the general paralysis of dementia.

#### PROLONGED UTERO-GESTATION.

DR. MRAVLAG reported a case, which he had recently observed, in which utero-gestation was continued six weeks beyond the full term. At a period when labor should have normally occurred, pains came on, but soon ceased. The child continued to show signs of vitality until its birth, which was effected with considerable difficulty. On extrusion, it was found to be a hemicephalus, measuring twenty-three inches in length, and weighing twelve pounds.

DR. MUNDÉ instanced a case in which pregnancy was continued for three hundred and forty-one days.

DR. NOEGGERATH stated, that according to Prussian State Law, three hundred days was allowed as the normal duration of pregnancy. But several observers, among them Kilian and Stein, had reported cases in which gestation had continued for a considerably longer period. The infants in those cases were, as a rule, quite small.

#### PREGNANCY COMPLICATED BY THE PRESENCE OF AN OVARIAN CYST.

DR. NOEGGERATH narrated a case of this kind. When he saw the patient for the first time, she was four months pregnant. An examination revealed the presence of two tumors—one to the right, the other to the left of the umbilicus. Palpation elicited the occurrence of unmistakable contractions in the tumor of the right side, whereas the other tumor was found to present fluctuation. The latter growth could also be felt in Douglas's pouch. The physician in charge performed an exploratory puncture of the supposed cyst, but was unable to draw off any fluid. He employed a syringe armed with a large canula. A second attempt of this kind also proved negative, the needle coming upon a hard mass. Following these procedures the tumor gradually diminished in size, and excited a suspicion of extra-uterine pregnancy, although a positive diagnosis of this kind was not made.

Dr. Noeggerath then made a third puncture, using, however, a needle of very fine calibre. This time a somewhat viscid fluid was withdrawn. It proved to be the fluid characteristic of ovarian cysts, and thus positively established the first diagnosis.

In this connection he took occasion to say that needles with sharp-cut edges very readily became filled with blood, coagulation of which prevented the further entrance of fluid. It was this circumstance which had brought about the negative results of the first two trials in the present case. The needles which he was in the habit of using for purposes of exploratory puncture had rounded points, and thus facilitated the entrance of liquids.

In reply to a question from Dr. Mundé, Dr. Noeggerath said that when we were dealing with large cysts, punctures per vaginam should not be made, but that they should be practised high up at the abdomen. In this way the exit of fluid into the peritoneal cavity was most effectually prevented.

#### DIPHTHERITIC STENOSIS OF LARYNX—TRACHEOTOMY—RECOVERY.

DR. CAILLÉ reported a case of the above occurring in a child, aged four years. When first seen the little girl had diphtheritic patches on both tonsils. There was swelling of the submaxillary glands, and the constitutional symptoms of a moderately febrile disease. Three days later, both local and general symptoms had subsided, and the child was apparently well. She remained in this condition for five days, when she rather suddenly developed a hollow-sounding, voiceless cough, and complained of dyspnœa. There was a slight febrile movement, but no visible membranes in the fauces.

Tracheotomy was performed, and although the incision assumed a diphtheritic appearance, the child quickly recovered. He thought that in this case the inflammatory process had either slowly and insidiously crept from the fauces into the larynx, or that two separate attacks with different localization had been present.

---

*Stated Meeting, June* 24, 1881.

DR. SCHARLAU, PRESIDENT, IN THE CHAIR.

SPINAL APOPLEXY IN A CASE OF CHRONIC MYELITIS.

DR. RUDISCH related a case of the above as follows: The patient was a man, fifty years of age (he was exhibited before the society), and gave a well-marked history of acquired syphilis. Some three years ago he suddenly fell to the ground, and was unable to move his legs. There was also a burning sensation in his bladder. On the day following this accident, he was able to move his legs slightly. The urine had to be drawn off with a catheter. Three weeks later he was again able to walk, but still felt weak and unsteady. His bowels had moved spontaneously about every fifth day. He continued to improve, but suffered occasional relapses.

At present there is a partial paralysis of both legs, the right one being especially wasted by atrophy. Occasional muscular contractions take place. Tonic and clonic spasms likewise occur on flexion. There is some tremor. The bowels are irregular in their action. There is no formication or other disturbance of sensation. Galvanic and faradic reaction are both increased. The tendon reflex is considerably exaggerated on the right side. He was inclined to regard the case as one of chronic myelitis, involving the anterior and lateral columns. The probable seat of the hemorrhagic lesion was in the lower portion of the dorsal part of the cord.

DR. JACOBI differed from Dr. Rudisch in his interpretation of the case. He thought that the rapid improvement in the patient's condition militated against the idea of a hemorrhage. For a bloody effusion would hardly be absorbed before the fourth or fifth day. He believed that obstruction of circulation had interfered with the blood-supply of a limited territory of the spinal cord. Probably a specific endarteritis was at the bottom of it all. Heubner had described just such cases; and he had seen several himself. There had variously been either absence or presence of premonitory symptoms in the different cases. Wunderlich had described an instance of this kind with distinct prodromal symptoms, in Volkmann's series of clinical lectures.

TRAUMATIC OPHTHALMOPLEGIA.

DR. GRUENING showed a young man who was suffering from an ophthalmoplegia of the left eye. Some time ago the patient had been struck with the fist, the blow falling directly upon the left eye. On his arrival at home he was found to be blind. An examination soon afterward revealed extensive ecchymoses and paralysis of the lid.

The eye was immovable, indicating paralysis of the motor oculi, abducens, trochlear and optic nerves. The pupil showed no reaction to direct light, but a slight one on illumination of the sound eye. The ophthalmoscope revealed no point of special interest.

At present the patient was able to slightly move his eye, but the sound pupil showed no reaction on exposing the other one to direct light. The functional activity of the optic nerve was, therefore, completely abolished on the left side, whereas the oculomotor nerve was only in a condition of paresis. He thought that the orbital pyramid must have sustained a fracture, resulting in a tearing of the optic nerve. The effusion of blood doubtless explained the other symptoms, by the pressure it exerted upon the nerves which course through superior orbital fissure. The prognosis in this case was not favorable. His treatment consisted in the use of electricity and the exhibition of iodide of potassium and strychnia, the latter hypodermically.

In answer to a question from Dr. Jacobi, asking what results were to be expected from the use of strychnia, Dr. Gruening stated that this drug was credited with a specific action on the retina. Personally, however, he had not hitherto seen any such action.

DR. JACOBI thought that strychnia might prove serviceable later on in the course of the disease, when anæmia became manifest.

ABSCESS OF THE BROAD LIGAMENT.

DR. HEINEMANN presented a specimen illustrating the occurrence of an abscess in the left broad ligament. The patient was twenty years old and single. About one year ago a tumefaction was first noticed. Injury had not preceded the development of the disease. She was admitted to the Roosevelt Hospital, where the gradually growing abscess was opened by an incision above Poupart's ligament. Pus and fecal masses escaped after the operation, and the patient finally died of exhaustion.

At the autopsy an abscess was found starting from the left broad ligament, and perforating into the pelvic cavity. Owing to the presence of extensive adhesions, the abdominal cavity had not become involved. An intestinal communication, which had undoubtedly existed during life, was not discoverable.

RUPTURE OF A FATTY HEART.

DR. HEPPENHEIMER presented a specimen of the above, which he had removed from the body of a woman who had died suddenly. The left ventricle showed a rupture, and the entire organ was altered by fatty changes.

FIBROUS CYSTO-SARCOMA OF THE BREAST.

DR. JACOBI presented a specimen, consisting of a tumor about the size of an English walnut, which he had removed from the breast of a young lady aged sixteen years, a short time ago. The growth weighed five hundred and forty-five grammes, and was mainly composed of a firm stroma surrounding serous cysts. No swellings had been found in the axilla.

ATROPHY OF FINGER-NAILS.

DR. SEESSEL reported the occurrence of ungual atrophy occurring in a child, and recently observed by him. After recovery from an attack of croupous pneumonia, the patient developed several abscesses. One of them was situated in the axilla, and, by pressing upon the nerves, caused an atrophy of the finger-nails. Regeneration of the atrophied nails subsequently took place. This was a purely trophic, in contradistinction to the so-called vaso-motor disturbance.

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, October* 20, 1881.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

### RECLAMATION BY DR. DÉCLAT.

THE PRESIDENT acknowledged the receipt of a volume published by Dr. Déclat in 1865, in which was set forth a new therapeutical use for carbolic acid. In a paper read by Dr. Sims, at the last stated meeting of the Academy, allusion was made to certain advantages which were to be gained by prompt operations within the peritoneal cavity, and they were largely the outgrowth of the knowledge which the profession had derived of antiseptic measures embraced under the general term Listerism, a word now in common use. The volume was accompanied by a letter which he had received from Dr. Déclat, containing a reclamation, with considerable evidence in support of the assertion that he antedated in priority the observations and publications of Lister by several years. The book and the letter would be placed in the archives of the Academy, where they could be consulted, thus affording opportunity to study Dr. Déclat's claims, and each could then settle the question in his own mind.

The following is an abstract of Dr. Déclat's letter. It was addressed to the President of the New York Academy of Medicine, and was written to establish two points:

*First.*—That he claimed the priority of the so-called antiseptic method.

*Second.*—That the system of Lister was both imperfect and incomplete.

"His first publication, in 1865, which he sent to Sir James Simpson, of Edinburgh, was the starting-point of the first application of carbolic acid by Mr. Lister in that city in 1867, two years later, and *six* years after his public application of the remedy at the Hôpital St. Jean de Dieu, in the presence and with the co-operation of Dr. Gras and Professor Maisonneuve, who took it upon himself to communicate it to Professor Simpson, who accused Lister of plagiarism in claiming that discovery; and Dr. Sanson, the authorized translator of Lister's works, admits my claim."

Dr. Déclat presented to the Academy his book written in 1865, and also referred to an extract in Pasteur's work on beer-fermentation (p. 44), where that eminent scientist clearly defined his rights to priority, after having alluded to Mr. Lister. The extract says: "Dr. Déclat has created a new system of medicine founded on the employment of one of the best-known antiseptics (carbolic acid), namely, that transmissible diseases are each the product of a special ferment, and that medical and surgical therapeutics must try and prevent the penetration of ferments coming from without into the liquids of the economy, or, if they have penetrated, to find antiferments to destroy them without diminishing the vitality of the histological element of liquid and tissues."

Dr. Déclat also referred to the *Bulletin Officiel des Comptes Rendus de l'Académie des Sciences de Paris, du* 11 *mars*, 1878, in which Professor Sédillot saw fit, a majority of the Fellows being present, to establish the priority of his claim. Dr. Déclat continued: "I have said that the Lister method is imperfect in two ways: First, because in most wounds and operations we should put aside the carbolic spray, with its many inconveniences, and replace it by a direct cauterization of the tissues, operated upon by means of a solution of about equal parts of carbolic acid and alcohol, followed by a carbolic dressing. The Lister method is incomplete, because it does not realize the second part of the antiseptic therapeutics, as it only partially prevents the penetration of ferments from the exterior. Neither Mr. Lister nor Dr. Sims (I think) has done anything to destroy them once they have penetrated into the liquids of the economy, and there is septicæmia or pyæmia; but this addition to the antiseptic treatment is the more important since it applies both to medicine and surgery. It consists in introducing with impunity into poisoned liquids, tissues, or organs, antiferments and chemically pure *acide phénique, sulfo-phénique, iodo-phénique*, and *acide salicylique* by means of draughts (enemata), and, above all, by hypodermic injections in large doses. The greater part of the accidents that have happened in surgery can be traced to the presence of volatile bodies, *acide crézilique, l'acide rosacique*, and *rasoline*, which are present even when the carbolic acid is in crystals. In the hands of the followers of Lister a patient stricken with septicæmia is not curable; while the patient has many chances of recovery by the internal antiseptic treatment."

DR. A. C. POST exhibited plaster-casts illustrating the condition of the hands before and after the operations for the relief of the deformities, in a case which he had already reported to the New York Surgical Society.

DR. PASSMORE, of Brighton, England, was introduced to the Academy, and invited to a seat upon the platform.

### LESIONS OF THE ORBITAL WALLS AND CONTENTS DUE TO SYPHILIS.

DR. C. S. BULL read a paper on the above subject, in which he restricted his remarks to the study of the lesions of the bones, and the adipose and connective tissues of the orbit. These lesions were not a common, though by no means a rare manifestation of syphilis. The lesions considered were osteitis, periostitis—singly and combined, periostosis, hyperostosis, exostosis—of which two or more might coexist, caries and necrosis involving perhaps only a small portion, and possibly the entire thickness of the bone invaded. According to most authorities those lesions belonged to the late manifestations of the disease; but Dr. Bull thought that they might occur earlier than had usually been supposed. They were more common in hereditary than in acquired syphilis, and in warm than in cold latitudes. The earlier periostitis was much less indolent than that which appeared later, and was never followed by exostosis or hyperostosis.

The symptomatology of these different lesions was illustrated by cases, and the treatment of each variety was considered in detail. Mercury and iodide of potassium were the drugs chiefly used in the medicinal treatment, and in some cases it had been found necessary to reach very large doses of iodide of potassium before the symptoms of the disease began to yield.

DR. J. W. S. GOULEY complimented the author of the paper upon the value and completeness of his contribution, with reference to both the pathology and symptomatology of syphilitic lesions of the orbit, and then proceeded to speak of treatment, both medical and surgical.

With reference to treating the early manifestations of syphilis with free doses of mercury, and

later with full doses of iodide of potassium, advocated by Dr. Bull, he believed that a great deal more harm than good followed the indiscriminate use of mercurials and iodide of potassium. He thought it was unnecessary to touch the gums, and, especially, the patient should not in the least be ptyalized. Mercury should be given in sufficient quantity to produce certain effects without producing ptyalism. In none of his syphilitic patients did he give more than minute doses, by the mouth, of the corrosive chloride or the biniodide of mercury, accompanied by inunction, and he never expected to see any symptoms of ptyalism. He often began with one-fiftieth of a grain of the corrosive chloride, using, at the same time, inunction first upon one side of the body, and then the other, watching its effect closely, and suspending its use every month or every two months. He uses the iodide of potassium still more cautiously, for heroic doses may produce most alarming symptoms, and give rise to diseases which become absolutely incurable, such as sclerosis of the kidneys. He had known a number of cases in which death was caused by the administration of the iodide of potassium for months—for six months, beginning with a drachm daily, and gradually increasing the quantity until the patients took an ounce of the drug daily. Those were abuses which should cease, and which might be considered as malpractice.

A very distinguished English surgeon had passed to the other extreme, by saying that he could produce all needed results with five-grain doses. Dr. Gouley believed that such doses were too small. He thought that twenty grains, given three times a day, or fifteen grains four times daily, would accomplish all that was done in Dr. Bull's cases by the administration of two drachms or more daily.

With regard to surgical treatment, he would not be willing to undertake an operation upon any case of orbital necrosis until the patient had been kept under the influence of medicinal treatment for some time, and his general condition improved as much as possible, except in certain cases where abscesses existed. In those cases he would give free vent to the pus, remove loose pieces of bone, and then put the patient upon constitutional treatment.

With reference to exostoses, which were usually late symptoms, there was no doubt concerning the propriety of their removal by surgical means.

Dr. Knapp said that he had no great experience on the subject of Dr. Bull's instructive paper, yet a few cases which he recollected might be worth relating. He had seen, several times, *acute circumscribed periorbitic swelling* in syphilitic persons, who recovered quickly under mercurial treatment.

He had in mind a case of *chronic periostitis* of the inner part of the superior orbital margin, which for two years had occasionally formed an abscess, opened, and discharged a puriform liquid. The syphilitic origin was not clear, yet the patient was cured by iodide of potassium.

Another case had greatly excited his interest. It was that of a man over fifty years of age, who had contracted syphilis when about twenty. Several years later the region of his brows began to swell, and in the course of years, with repeated inflammatory aggravations, developed into a hard, uniform prominence—a true *hyperostosis*, constituting a marked deformity, upon which mercurials and iodides had no influence whatever.

Another case was still more vividly in his mind. A man had had a primary affection about fifteen years ago; then, in the course of years, different manifestations of unmistakable constitutional syphilis, among which, periostotic swelling of several bones. At last he had *diffuse periostitis of the orbital walls*, especially the upper—not very painful to the touch, but with intense, spontaneous pain. There was exophthalmus, but no lesion of the eye—in particular no neuro-retinitis. Complete and permanent recovery was obtained by a course of mercurial treatment, chiefly inunction, for several months.

Dr. O. D. Pomeroy had recently had a case which illustrated one point in the subject. The initial lesion of syphilis occurred about six months before the development of an abscess just beneath the superciliary ridge, and extending into the roof of the orbit, without displacing the eyeball. The patient had abscesses in other regions, but otherwise the syphilitic symptoms were but few. He opened the abscess, found dead bone, placed the patient upon constitutional treatment, and recovery was exceedingly rapid.

With reference to the size of dose of different remedies, he gave the least amount possible to produce the desired effect. He regarded the $\frac{1}{14}$ of a grain of the bichloride of mercury as a large dose. Intermittent inunction with mercurials he regarded as beneficial. His belief in the efficacy of the iodide of potassium was "extremely shaky." Small doses, according to his observation, affected some patients in a marked manner.

With regard to etiology, he thought that injury, in many cases, excited the disease into virulent activity. In the treatment of diseases of the tear-duct he had frequently seen orbital lesions, and could corroborate Dr. Bull's statement that sequestra, as a rule, were absent in cases of necrosis in that region.

The President, with reference to excessive doses of iodide of potassium, was rather surprised at the strong statements made by Dr. Gouley, and yet he was well aware that very large doses of the drug were frequently given in the city of New York. He then referred to a case of ataxia due to syphilis, in which there was complete paraplegia, with paralysis of the bladder and rectum. To that patient he gave a drachm of the iodide of potassium three times daily, beginning with twenty-grain doses, and an entire cure had been effected.

In another case he was giving large doses, but should begin to diminish the quantity, in consequence of what he heard during the discussion.

Dr. Gouley had for ten years, and in accordance with a suggestion which he received from Dr. Meredith Clymer, been using the iodide of sodium instead of the iodide of potassium, believing that it was the potassium, and not the iodine, which was the toxic agent. He had found that large doses of iodide of sodium were much better borne than were equally large doses of iodide of potassium; and besides, the sodic salts in the same quantity had no tendency to produce sclerosis of the kidneys. He condemned the excessively large doses of iodide of potassium so frequently given, and believed that the physician who gave an ounce of the drug daily, and continued it for weeks and months, was guilty of malpractice. The syphilis might be cured, but the patient very likely would be killed by the chronic interstitial nephritis developed by this excessive and prolonged administration of the iodide of potassium.

As was well known, there were patients who could not tolerate the minutest doses of iodide of potas-

sium, while there were others who required very large doses. In his belief the latter were more likely to be harmed by the drug, for their stomachs tolerated the large doses, but in the end their kidneys suffered. He had had patients who could not bear a single grain at a dose, and others who required very large doses, but the latter had always given him great anxiety. He had known a most violent hæmaturia to follow the use of forty grains of the iodide of potassium three times a day, and continued for two weeks. The symptom disappeared within a few days after discontinuing the drug, and afterward he was careful to give smaller doses.

Dr. A. W. Stein believed that it was impossible to treat every case of syphilis without touching the gums, however great the precaution taken might be. Of course, no physician would administer a drug to the production of its physiological effects when its therapeutical effects could be produced by much smaller doses. Salivation should be avoided if possible; but some patients were so susceptible to the influence of mercury that even the smallest doses would affect their gums. Further than that, he had treated cases at the Charity Hospital in which the secondary symptoms did not yield until the gums were slightly touched, and he had not seen any harm follow such a manifestation of the physiological effect of the drug.

With reference to the iodide of potassium, his practice was to begin with ten-grain doses. He had seen patients who could not bear five-grain or even three-grain doses; but there were those who could bear much larger doses than ten grains, and whose symptoms would not yield until the larger doses were reached. In cases of rapidly progressing osteitis and periostitis, or other grave manifestations of syphilis, he was not disposed to trifle with the disease by giving small doses of the iodide of potassium, especially when many cases were seen in which it was only when drachm doses were reached that the symptoms began to yield, and then the recovery was rapid. He did not doubt that the prolonged use of large doses might do damage to some of the organs of the body; but it was unnecessary either to resort to them in all cases, or to continue them for a great length of time. Perhaps we had gone to the extreme in using large doses, but he hoped that we should not fall back to the old method of using insufficient doses.

Dr. E. H. M. Sell referred to a case in which iodide of potassium invariably aggravated the symptoms. Iodide of sodium was substituted, and, although administered in only five-grain doses three times daily, the gummata and other manifestations of syphilis rapidly disappeared. He disapproved of the use of excessive doses of the iodide of potassium.

Dr. Bull, in closing the discussion, said that, in the first place, he had no intention of starting a therapeutical discussion; and secondly, that he did not wish to be understood as underestimating the danger attending the administration of too much mercury and iodide of potassium. For many years he had not produced any marked symptoms of salivation. Nor, on the other hand, should he consider himself guilty of malpractice if he should administer half an ounce of the iodide of potassium three times a day, if such doses were necessary. There were cases which would not yield to small doses, and what had been called excessive doses were necessary to effect a cure.

Granted the existence of sclerosed kidneys, associated with a corresponding change in the liver; post-mortem in a syphilitic subject, he believed that the renal change and the condition of the liver were due to the syphilis rather than to the potassium iodide.

The Academy then adjourned.

## Correspondence.

### ON GUITEAU'S INSANITY.

To the Editor of The Medical Record.

Dear Sir—In a late number of The Record (October 22, 1881), you have the following passage: "He has that form of monomania which has been described by the German writers as *primäre Verrücktheit*, and by others as partial intellectual insanity."

The term *primäre Verrücktheit* is not in the least identical with the term "monomania," which might be rather rendered by *partielle Verrücktheit*, as it is a partial insanity, more especially by that form of partial insanity that has been described as paranoia (Kahlbaum). But it would be in the interest of an exact diagnosis if the term monomania, of Esquirol, which has already early been criticised by Foville and Prichard, would be altogether disused. Most of the monomanias described by Esquirol, such as kleptomania, pyromania, etc., are only symptoms of larger groups of insanity, such as hysterical and epileptical insanity, for instance.

The psychological school of alienists (Guislain, Griesinger, etc.) had the opinion that all insane persons are passing through certain well-characterized phases of psychopathological phenomena; those stages being: (1) melancholia and mania, or the emotional stage; (2) *Verrücktheit* (secondare), delusional insanity, or the intellectual stage; (3) *Blodsinn* (dementia), the negative stage, or the stage of general deficiency.

This division had its foundation in the psychologi- theories then in vogue, being based on the entity of the soul and its three principal functions, emotion, thought, and will. There is a form of insanity that is congruent to this description, the vesania typica.

How erroneous the belief is that aberration almost always begins with melancholy (Guislain and Griesinger), may be seen from the following statistical table of Witkowski (*Berl. klin. Wochenschrift*, No. 50, 1876): In sixty-five cases the premonitory symptoms were as follows—In 19 patients, melancholy; in 17 patients, mania; in 26 patients, delusional insanity (*Verrücktheit primäre*); in 3 patients, dementia.

Modern alienists, studying the forms of insanity from a clinical point of view, have established certain groups of clinical entities, among which *primäre and originäre Verrücktheit* has found a well-recognized and important place. The term *primäre Verrücktheit* (idiopathic disease) is used in contrast to *secondäre Verrücktheit* (only a symptomatic stage).

To discuss the particular form of insanity from which Guiteau is said to suffer is premature, before a detailed and well-authenticated biographical sketch is published, but it may be safely surmised, from facts known so far, that his insanity, if such will be proved, has to be one of the following two: either *primäre Verrücktheit* (delusional insanity), or diathetic and hereditary (neurotic) insanity.

J. J. Friedrich, M.D.

332½ East Fiftieth Street, New York.

[Partial insanity, monomania (of Prichard), and delusional insanity are used as synonymous terms.—Ed.]

To the Editor of The Medical Record.

Dear Sir: The editorial on the question of Guiteau's insanity in your recent issue, assumes seriously that Guiteau had delusions—shall I say insane delusions. What evidence is there in support of this assumption? If I take up his own published narrative of the motive or motives that impelled him to kill President Garfield, I find that he "removed" his victim "as a political necessity." What was this political necessity? It was the necessity of uniting the Republican party under Stalwart control. He committed a crime for a political end, and with the secret hope, as I suspect, of profit to himself should that end be accomplished. Whether he succeeds or not, is there any appearance of delusion either in the conception of his end, or in the method by which he sought to attain it? It does not seem to me that there is.

It is true Guiteau professes to have acted under "Divine pressure." I take note of this, but I call to mind also that there is no small share of cant in this broad country.

It is too early to make up our minds—it is positively too soon to pass judgment on the mental quality of Guiteau's deed. But it is not too early to get a mental hold of certain elementary, yet necessary, truths respecting the relations of insane people generally to the question of legal responsibility.

In the first place, it is an error to infer, as do some physicians, and many, perhaps the majority, of laymen, that the insane are not responsible for their acts. This is too sweeping an inference. In relation to the question of legal responsibility, the insane need to be classified under two distinct heads, viz.: 1, Insane people more or less responsible; 2, insane people not responsible.

In the second place, the ground of all classifications of *the insane* relative to their legal responsibility lies in the following question: Is the criminal act, so to speak, the *logical*, or, if you choose, *psychological* outcome of the agent's delusion, of his hallucination, of his insanity, in short? If the evidence affirms this, the agent is not responsible; if it negatives this, he is responsible, though *quo ad* his insanity, the degree of his responsibility remains to be decided.

To establish the innocence of an indicted offender who interposes the plea of insanity as his chief defence, it is not enough to prove that he was insane at the time of his offending; there should be, also, reasonable proof, in my judgment, that his offense was the logical or psychological outcome of his *insane* notions, beliefs, impulses.

James J. O'Dea, M.D.

Stapleton, Staten Island, N. Y.

---

Dr. Talmy, an eminent surgeon of the French navy, has gone to the coast of Senegal to make a study on the spot of the recent terrible outbreak of yellow fever. Dr. Talmy's direct object is to determine the application to this disease of M. Pasteur's new theory of specific inoculation as a preventive against epidemics.

Leprosy in New Brunswick.—Dr. Tache, Deputy Minister of Agriculture, who was sent by the Government to the Tracadie (New Brunswick) Lazaretto to make a report on leprosy, states that so little is the disease understood, that it will be some time before a report can be prepared. He found the disease diminishing, there being at present only nineteen lepers.

# Obituary.

## BENJAMIN FRANKLIN BACHE, M.D.,

MEDICAL DIRECTOR AND COMMODORE, U. S. NAVY.

Medical Director Benjamin Franklin Bache, a great-grandson of Benjamin Franklin, and for nearly sixty years an officer in the United States Navy, died at his residence, Brooklyn, November 1st, after an illness of only two weeks. Dr. Bache was born in Monticello, Va., February 7, 1801, and so was in the eighty-first year of his age. He was a grandson of Richard Bache and Sarah Franklin Bache, the only daughter of Benjamin Franklin.

Dr. Bache was graduated from Princeton College when only eighteen years old, and from the medical department of the University of Pennsylvania four years later. He entered the United States Navy as Assistant Surgeon in 1824, a year after his graduation, and in 1828 he was promoted to the rank of Surgeon. From 1838 to 1841 he was Fleet Surgeon of the Mediterranean squadron, and he was in charge of the Naval Asylum in Philadelphia from 1845 to 1847. He was Fleet Surgeon of the Brazilian squadron from 1848 to 1850; was in the Naval Hospital in New York from 1850 to 1854, and was Director of the laboratory of the Brooklyn Navy Yard from 1855 to 1872. He was retired February 1, 1863, and in 1871 he was appointed Medical Director, with the relative rank of Commodore. While he was engaged in the laboratory of the Brooklyn Navy Yard, in 1861, at the outbreak of the civil war, his knowledge as a chemist, and his unquestionable honor, made a valuable help in the time of his country's need.

Finding that the supplies and drugs then furnished to the Government were poor in quality and deficient in weight, he undertook to reorganize the department. He thus met with determined opposition from many influential persons, who hoped to profit by the unlawful schemes of the contract system, and obstacles were thrown in his way that would have discouraged most men. He took the samples that were furnished by contractors, analyzed them, and compared them with those actually delivered, and finding, in many cases, that they were not as had been represented he condemned them, and thus saved the Government millions of dollars. The laboratory, under Dr. Bache's administration, became one of the most thoroughly equipped and efficient branches in the service. Dr. Bache was quiet and modest in disposition, possessing a great range of knowledge. There were few subjects with which he was unfamiliar. As a student, a chemist, a traveller, and an observer he was received in social circles everywhere with profound consideration. He was a brilliant conversationalist, and recited by the hour experiences and observations in his long life of the most entertaining character. He bore a strong resemblance to his distinguished ancestor; and his side face was almost the counterpart of that shown in the best pictures of Benjamin Franklin. He was severe in his detestations of shams of every kind, and never hesitated to denounce them, without regard to person or position. He leaves a widow and three married daughters, the wives of Drs. Bates and Bogert and Capt. Charles L. Huntington, all of the United States Navy. His sister is the wife of Dr. E. R. Squibb, of Brooklyn, N. Y.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October* 30, 1881, *to November* 5, 1881.

KOERPER, E. A., Capt. and Asst. Surgeon. Relieved from further duty at Yorktown, Va., and to proceed to Plattsburg Barracks, N. Y. S. O. 191, Department of the East, November 3, 1881.

SKINNER, J. O., Capt. and Asst. Surgeon. Relieved from duty as Acting Medical Purveyor in the field, and to proceed to his proper station, Whipple Barracks, A. T. S. O. 123, Department of Arizona, October 26, 1881.

HALL, W. R., Capt. and Asst. Surgeon. Granted leave of absence for one month. S. O. 224, Department of the Missouri, November 2, 1881.

ARTHUR, WM. H., First Lieut. and Asst. Surgeon. Relieved from duty at Fort Sanders and assigned to duty at Fort Washakie, Wyo. T. S. O. 110, Department of the Platte, October 29, 1881.

The following named medical officers will report in person without delay to the Commanding General Military Division of the Atlantic, for temporary duty with regiments about to change stations. Upon completion of their duty with these regiments, to report by letter to the Surgeon-General: First Lieuts. and Asst. Surgeons E. C. CARTER, H. I. RAYMOND, T. J. C. MADDOX. S. O. 248, A. G. O., November 3, 1881.

APPOINTMENTS

To be Assistant Surgeons, with the rank of First Lieutenant:

EDWARD C. CARTER, of New York, October 22, 1881, vice PHILLIPS, deceased.

HENRY I. RAYMOND, of New York, October 22, 1881, vice OTIS, promoted.

THOMAS J. C. MADDOX, of New York, October 22, 1881, vice SMITH, resigned.

RICHARD W. JOHNSON, of Minnesota, October 22, 1881, vice JAQUETT, promoted.

G. O. 77, A. G. O., October 31, 1881.

## Medical Items and News.

CONTAGIOUS DISEASES — WEEKLY STATEMENT. — Comparative statement of cases of contagious diseases reported to the Sanitary Bureau, Health Department, for the two weeks ending November 5, 1881.

| Week Ending | Typhus Fever. | Typhoid Fever. | Scarlet Fever. | Cerebro-spinal Meningitis. | Measles. | Diphtheria. | Small-pox. | Yellow Fever. |
|---|---|---|---|---|---|---|---|---|
| Oct. 29, 1881. | 0 | 36 | 121 | 5 | 12 | 101 | 22 | 0 |
| Nov. 5, 1881. | 0 | 32 | 125 | 3 | 18 | 98 | 16 | 0 |

CASES OF NERVE-STRETCHING.—In the Manchester Royal Infirmary the operation of nerve-stretching has been lately performed *(Lancet)* by Mr. F. A. Southam upon three patients. These were in cases of idiopathic lateral sclerosis, locomotor ataxia, and clonic spasm of facial muscles. In all cases considerable relief was obtained.

THE GROWTH OF MEDICAL LANGUAGE.—In an introductory address delivered by Dr. G. Vivian Poore. at the opening of University College, London, the following from Cowper is made the text of some very sensible remarks:

> "Knowledge and wisdom far from being one,
> Have ofttimes no connection. Knowledge dwells
> In heads replete with thoughts of other men;
> Wisdom in minds attentive to their own.
> Knowledge . . . . . .
> Till smoothed, and squared, and fitted to its place,
> Does but encumber whom it seems to enrich.

"There is one branch of medical knowledge," said the speaker, "which most certainly 'does but encumber whom it seems to enrich,' and this branch is medical language.

"The unwieldy proportions which this cumbersome branch of medical knowledge has assumed, may be judged of by the dictionary of Medical and Scientific Terms which is now in course of publication by the New Sydenham Society. This dictionary already consists of eight hundred closely printed, large octavo pages, and the compilers have yet reached only the third letter of the alphabet. At the present rate the completed work will consist of over 8,000 pages, containing more than 300,000 terms!"

HEALTH OF SCHOOL CHILDREN AS RELATED TO OUTSIDE STUDY AND RECREATION.—Dr. L. B. Tuckerman, of Cleveland, O., sends us the following notes in regard to the health of the eight hundred pupils in the Cleveland High School. They were the results of personal investigation by a physician. "The most important fact developed," he says, "was the relation of ill health to the number of hours spent in study outside of school, and that it takes a girl, on the average, longer to do the same amount of mental work, thus dividing them into four classes—those that study less than two hours at home, those that study two hours or less than four, four hours and less than six, six and over, we have:

| | 0-2 | 2-4 | 4-6 | 6- |
|---|---|---|---|---|
| Boys.....per cent. | 25 | 65 | 5 | 3 |
| Girls.....per cent. | 8 | 47 | 38 | 6 |

"The number of the boys was too small to base any definite conclusions upon, but with the girls, one hundred and eighty-six in number, the facts were as follows:

| | 0-2 | 2-4 | 4-6 | 6- |
|---|---|---|---|---|
| Health poorer while at school.....per cent | 29 | 70 | 93 | 100 |
| Health very poor while at school.....per cent. | 14 | 40 | 66 | 100 |
| Appetite deranged while at school.....per cent. | 7 | 44 | 47 | 69 |
| Sleep deranged while at school.....per cent. | 7 | 18 | 37 | 69 |
| Troubled with headache while at school..per cent. | 22 | 62 | 81 | 100 |
| Troubled with back- or side-ache while at school, per cent. | 14 | 24 | 57 | 45 |
| Troubled with weak eyes..... | 29 | 39 | 36 | 42 |
| Eyes failed since the pupil entered the High School | 14 | 13 | 18 | 17 |
| Menstrual symptoms were known.....No. | 5 | 40 | 31 | 9 |
| Menses same while at school.....per cent. | 80 | 50 | 19 | 67 |
| Menses deranged while at school..... per cent. | 20 | 50 | 81 | 33 |
| Menses frequent or profuse while at school, per cent. | 20 | 28 | 26 | 11 |
| Menses scanty, irregular, painful ..... | .. | 35 | 71 | 33 |

"Cases where the menses were both frequent, or profuse and painful, were tallied simultaneously in each class, hence the apparent discrepancy in the percentages.

"The gain in health as the pupils indulge more freely in social relaxation is correspondingly marked. The parents of seventy-six of the one hundred and

eighty-six girls, attributed their trouble in part to the stair-climbing. The irregularity of meals, necessitated by the one-session system, the worry about rank and examinations, were assigned as causes by others."

THE ALLEGED INCREASE OF INSANITY.—There were in Great Britain on January 1, 1880, 73,113 insane. This is an increase of 1,922 during the previous year. The increase, however, is due in part to the fact that many pauper insane have been transferred from almshouses to asylums. The Lunacy Commissioners have prepared a new tabular statement, which shows the ratio per ten thousand of persons admitted to lunatic asylums during the past twenty years. It is as follows: The number admitted per ten thousand in 1869 was 4.71; 1870, 4.54; 1871, 4.62; 1872, 4.59; 1873, 4.80; 1874, 5.03; 1875, 5.19; 1876, 5.30; 1877, 5.28; 1878, 5.36; 1879, 5.20; 1880, 5.19.

From these figures it appears that the steady proportional increase of insanity, which continued to 1875, has since then ceased to go on for the last five years. It may be that the maximum proportion of insane to the population in Great Britain has been reached.

IS THERE A SPECIFIC URETHRITIS?—Dr. P. Albert Morrow (*New York Medical Journal and Obstetrical Review*, September, 1881), asserts that the position of the virulists rests altogether upon pure hypothesis, and is wholly untenable, while all the facts—experimental, clinical, and pathological—are overwhelmingly in favor of the non-specific character of gonorrhœal inflammation. If the experiments of De Luca, and others of like character, showing that the clear, transparent liquid which escapes from the cervix becomes contagious, when from any cause whatever it becomes charged with purulent globules, are to be accepted as true, it is necessary to renounce for ever the idea of the specificity of gonorrhœal pus. In all specific diseases there is between the time of infection and the first expression of the disease a period of incubation. No incubation, properly so-called, characterizes gonorrhœa—no more than there is between the chilling of the feet and the appearance of coryza, as Ricord pointed out, or between the action of the exciting cause of bronchitis or pneumonia and the appearance of the suppurative symptoms. A drop of this same gonorrhœal pus, which may require two or three days to excite suppuration of the urethra, will develop such effect in a few hours when applied to the conjunctiva, showing that the so-called incubation depends, not upon the quality of the exciting cause, but upon the susceptibility of the mucous membrane. Another distinctive peculiarity is that a single attack of the disease confers almost complete security from another attack—a peculiarity precisely the opposite of what is observed of gonorrhœa. One attack seems to establish a predisposition to a second, and the more numerous the attacks the more easily the disease is contracted anew, showing its analogy with other catarrhal inflammations.

Again, the morbid poison of a specific inflammation once in action, continues until the textural predisposition to its special stimulus is exhausted, the patient is incapable of regenerating the poison or of being affected by it when exposed anew. Both of these conditions are negatived in the clinical history of gonorrhœa. Dr. Morrow ridicules the idea of the contagium lying dormant in the system for months, and capable of being awakened and revivified into dangerous activity under the influence of any cause, either of external or of internal origin.

The experiments made with gonorrhœal pus for the cure of panus, leave no possible doubt as to the interchangeable and identical nature of urethral and conjunctival inflammations. The experiments of Jaeger, Piringer, Van Roosbroeck, Walomont, Desmarres, Richard, and others, have proved conclusively that the same effect is produced upon the eye from whatever kind of purulent ophthalmia the matter of inoculation is taken—that the effect is still the same whether, instead of taking the mucopus from the eye, it is taken from the urethra. In Dr. Piringer's series of eighty-seven cases, the matter was taken from ophthalmia neonatorum in twenty-nine cases, from gonorrhœal ophthalmia in eleven cases, from the urethra of a boy three and a half years old in two cases, from acute ophthalmia (not gonorrhœal) in forty cases, from palpebral ophthalmia in two cases, from chronic ophthalmia in four cases. Van Roosbroeck employed indifferently pus from gonorrhœal, from infantile, and from purulent ophthalmia. The only difference observed in the effects of the matter from these various sources depended upon the activity of the inflammatory process which produced it.

The identity of the cause and nature of inflammations of the urethra and conjunctiva being thus demonstrated, he concludes, with Simon: "Obviously there is no sense, except one involving a *petitio principii*, in which the word specific can be applied to these communicable conjunctival inflammations, and if they are not specific, but common inflammations, where is the reason for believing that the communicability of gonorrhœa constitutes it a specific disease?"

DENTAL DIPLOMAS IN FRANCE.—A commission has been appointed by the Faculty of Medicine to report upon the study and practice of dentistry in France. They have decided to create a special dental diploma. Candidates for this will have to be twenty years old, must study dentistry two years in a school, and must have had one year's practical experience.

ON THE USE OF QUEBRACHO IN DYSPNŒA.—Dr. Andrew H. Smith's report to the Therapeutical Society (*New York Medical Journal and Obstetrical Review*, September, 1881) on the employment of this drug for the relief of dyspnœa, contains some points of interest. Of the thirty-two cases covered by this report, eleven were of spasmodic asthma, with or without emphysema and bronchitis. Of these, in nine cases the dyspnœa was notably relieved. In two cases of asthma, associated with bronchitis, no benefit resulted. One patient with emphysema and bronchitis, without asthma, was relieved. One with bronchitis, with obesity, was not relieved. Two with mitral insufficiency were not relieved. One with mitral stenosis was not relieved. One with hypertrophy, with dilatation, was not relieved. In two cases of cardiac disease (form not stated) the dyspnœa was relieved. In one case of fatty heart there was slight relief. Two patients with dyspnœa depending on Bright's disease, in one of whom pulmonary œdema was noted, were relieved. In one case of aortic aneurism, the dyspnœa was relieved till near the close. In one case of cancer of the lung, dyspnœa was relieved. In one case of tonsillitis, the dyspnœa, partly nervous, was relieved. In two cases of pneumonia it was relieved. One patient with hysterical dyspnœa was relieved. In one case of catarrhal phthisis, second stage, the dyspnœa was relieved.

In one case of catarrhal phthisis, third stage, it was not relieved. In one case of intermittent fever, with old pleurisy, the patient being an opium-eater, the dyspnœa was increased.

Thus, of the thirty-two cases of different diseases in which dyspnœa formed a prominent feature, this symptom was relieved to a greater or less extent in twenty-two; not relieved in ten; aggravated in one. Dr. Smith, in explaining the action of quebracho, thinks it acts upon the respiratory centre by blunting the sense of want of air, and thus mitigates the suffering from a deficient supply. The extremely disagreeable taste of the medicine and its tendency to produce nausea, are, however, serious drawbacks to its use by the mouth.

Vital Statistics of Massachusetts.—Some interesting facts connected with the death-rate and its causes in Massachusetts have appeared. They relate to the year ending December 30, 1880. The rates for the year per thousand were: births, 24.80; marriages, 8.71; deaths, 19.79.

The number of deaths in 1880 (namely, 35,292) was considerably in excess of that of any year in the previous quarter of a century. The very fatal epidemic of diphtheria has continued, with even a moderate increase over 1879; the diarrhœal diseases of infants have caused much greater mortality than for the preceding two years; the infectious diseases generally have risen to a higher number, and pneumonia has been excessively fatal. The greater number of deaths in 1880 has been recorded at nearly all ages, but to the greatest extent in infants and young children.

The order of fatality of the twelve causes producing the greatest number of deaths, places consumption easily at the head of the list as usual. Pneumonia is second, as it was the previous two years, and in 1874 and 1875; it was third in 1872, 1873, 1876, and 1877—always a leading source of mortality in Massachusetts. Cholera infantum, from having steadily fallen from the second place in 1872 and 1873, the third in 1874 and 1875, the fourth in 1876 and 1877, fifth in 1878, and sixth in 1879, has risen in 1880 to the third. Heart-disease was fourth. Diphtheria stands fifth—if croup were included with it the deaths would be 2,394 instead of 1,769, and its place would be third. Old age is sixth. Paralysis is now, for the fourth year, seventh. Cancer has risen from tenth. eleventh, and twelfth places to eighth, as it was also in 1879. "Cephalitis" was ninth in 1880; bronchitis, as in 1879, eleventh. Typhoid fever showed an extraordinary decline from the fourth place in 1872, sixth in 1873, seventh in 1874, eighth in 1875 and 1876, ninth in 1877 and 1878, to thirteenth in 1879, and has now risen again to tenth.

Digitalis not a Cardiac Stimulant.—Dr. Edward T. Tibbits (*Lancet*) argues against the modern theory of the action of digitalis as follows:

Digitalis used to be described as a cardiac sedative and depressant, and I believe, for all practical purposes, this is exactly the correct description at the present time. The reasons for such belief are as follows:

*First.*—Experiments prove as much its sedative action as any other, and, so far as I can make out, it is probably accidental whether, after poisonous doses, the heart is arrested in systole or diastole. Even supposing the stoppage took place in systole, that is only the condition said to be present in any form of fatal syncope.

*Second.*—In small doses it produces a feeling of depression and discomfort about the heart, with sometimes nausea or vomiting, if kept up for a time. In large doses, though arterial tension is at first increased, this soon gives way to lowered vascular tension.

*Third.*—Like many other narcotico-acrid poisons, it produces dilatation of the pupil.

*Fourth.*—Its action, as shown by clinical experience, is in many ways like that of such depressants as aconite, lobelia, tobacco, etc.

*Fifth*—It is of great value in cardiac hypertrophy (?), being second only to aconite.

*Sixth.*—Its diuretic action is probably due to dilatation rather than contraction of the small blood-vessels.

The Fresh-Air Habit.—Early impressions are very enduring, and can make useful habits as well as evil ones a sort of second nature. In order to forestall the chief danger of in-door life, make your children love-sick after fresh air; make them associate the idea of fusty rooms with prison-life, punishment, and sickness. Open a window whenever they complain of headache or nausea; promise them a woodland excursion as a reward of exceptionally good behavior. Save your best sweetmeats for out-door festivals. By the witchery of associated ideas a boy can come to regard the lonely shade-tree as a primary requisite to the enjoyment of a good story-book. "Or, mes pensées ne voulent jamais aller qu' avec mes jambes," says Rousseau ("Only the movement of my feet seems to set my brains a-going"), and it is just as easy to think, debate, rehearse, etc., walking as sitting; the peripatetic philosophers derived their name from their pedestrian proclivities, and the Stoic sect from their master's predilection for an open porch. Children who have been brought up in hygienic homes not rarely "feel as if they were going to be choked" in unventilated rooms, and I would take good care not to cure them of such salutary idiosyncrasies. Every observant teacher must have noticed the innate hardiness of young boys, their unaffected indifference to wind and weather. They seem to take a delight in braving the extremes of temperature, and, by simply indulging this penchant of theirs, children can be made weather-proof to an almost unlimited degree; and in nothing else can they be more safely trusted to the guidance of their protective instincts. Don't be afraid that an active boy will hurt himself by voluntary exposure, unless his chances for out-door play are so rare as to tempt him to abuse the first opportunity. Weather-proof people are almost sickness-proof; a merry hunting excursion to the snow-clad highlands will rarely fail to counteract the consequences of repeated surfeits; even girls, who have learned to brave the winter storms of our Northwestern prairies, will afterward laugh at "draughts" and "raw March winds."—Dr. Felix L. Oswald, in *Popular Science Monthly* for November.

An Antidote to the Venom of the serpent Bothrops has been discovered by M. de Lacerda. That gentleman states that a hypodermic injection of permanganate of potash will prevent the usually serious effects of previous injections of the poison.

American Public Health Association.—The ninth annual session of the American Public Health Association will be held at Savannah, Ga., November 29th to December 2d, inclusive.

# Original Communications.

## THE TRANCE STATE IN INEBRIETY: ITS MEDICO-LEGAL RELATIONS.*

By T. D. CROTHERS, M.D.,
HARTFORD, CONN.

In 1879 I read a paper before the American Association for the Cure of Inebriates, at their annual meeting, entitled "Cerebral Trance or Loss of Consciousness following Inebriety, based on a Clinical Study of Cases." The following are some of the conclusions which were drawn from this study:

1. Loss of memory and consciousness may come on in inebriety, and be accompanied by little or no evidence of the actual state.

2. This condition of the brain arises from complex causes, which require careful study, and particularly when crime is associated with inebriety. If the trance state is present, its medico-legal relations are of the greatest practical importance.

Up to that time no study had been made of this phase of disease associated with inebriety. Then I supposed that this peculiar psychological state was rare, and seldom seen in this disorder; also that it was some obscure form of epilepsy, the result of causes that were more or less accidental, and seldom developed in this way. Later studies in this direction indicate clearly that these cases are very common, and are distinct from epilepsy. This state, noted by a loss of consciousness and memory, without stupor, during which the patient acts and appears rational, and yet is a mere automaton, without memory or realization of his actual condition, is present more or less in all cases of inebriety. To test this clinically, I made a special study of sixty-two cases which came under my personal care—cases of inebriety that were of long standing, representing the middle and better classes of society, and studied as they came, without selection. Of this number, in ten cases the trance state was so prominent as to be recognized by friends, and considered a form of insanity. In twenty-eight cases these blanks of memory had been noted less prominently, as of shorter duration, and were termed drunken fits. In the remaining twenty-four cases these blanks were more or less indistinct, following stupor and intoxication, and only ascertained by a study of the symptoms. All of them gave evidence of acts which were unaccountable to themselves or friends, and of which they had no recollection. I propose in this paper to give some of the general conclusions which have been indicated from these and other clinical studies I have made, illustrated by the history of some very prominent cases, whose physiological and medico-legal significance cannot be overestimated. At the beginning it is important to recognize clearly the distinction between alcoholism and inebriety.

The term alcoholism does not correctly describe all the cases which suffer from excessive use of alcohol or its compounds, but denotes merely such cases as come directly from the toxic action of alcohol. Inebriety represents a special disease of the central nervous system, not caused by alcohol alone, but due to conditions of nerve-degeneration, of which alcohol may be only an exciting cause or symptom of the neurotic condition. As understood at present, inebriety is the disease, and alcoholism is only a group of symptoms noted in the latest stages of the disease. All my studies of these cases are based on the fact that inebriety is a disease originating in certain definite or complex causes, and progressing through regular stages of development on to recovery, chronicity, or death. Inebriety is a positive physiological disorder, and not a combination of habit, vice, and sin.

The trance state is only a phase or particular symptom of inebriety, in which certain brain-functions are arrested. Unlike some other forms of trance, nervous activity is not particularly concentrated in one direction, but is absolutely cut off in others. The combined action of a defective mental state with the effects of alcohol, in certain unknown stages, cause not only suspension of the memory, but of consciousness—a literal paralysis of certain brain-functions. It may appear at almost any stage of inebriety, notably in chronic cases, or in those recently attacked. The nature and phenomena of trance in general have been fully described by my friend, Dr. George L. Beard, and many of the vast fields of medico-legal and physiological interest outlined by him. This is the same physiological state coming from certain specific causes. In this special form of trance following inebriety, the succeeding facts may be considered, established, and confirmed by clinical studies:

1. The trance state is a common symptom in inebriety, in which the patient is without consciousness and recollection of present events, and gives no general evidence of his real condition. This may last from a few moments to several days.

2. This state is clear evidence of profound disturbance of the higher brain-centres, and is of necessity followed by impaired judgment and lessened responsibility.

3. This trance state will always be found associated with a particular neurotic condition, either induced by alcohol or existing before alcohol was used. In all chronic states of inebriety it will be found present in a greater or less degree. The first fact is supported by the evidence found in the history of every case of inebriety. The second will be clear from the history of the cases which will follow; and the third can also be established from the clinical histories. The cases presented are selected as typical, and also for the purpose of bringing out prominently the symptoms and medico-legal interest growing out of them. I shall confine myself to some of the most general clinical facts, without entering into any discussions of the pathology or nature of this state. The plan I have followed is to give, first, cases in which the mind acted along certain accustomed lines of thought and action in the trance condition; second, cases in which the mind displays unusual ranges of thought and action, referable to varied mental conditions; and third, cases in which the criminal impulse was prominent.

Case I.—*Trance following Inebriety—Automatic Recovery.*—A railroad conductor, aged forty-five. Parents farmers, and healthy; no evidence of inherited disease. He grew up a strong, robust boy, and at twenty-two went on the railroad as baggage-master. Ten years later he married and was promoted to a conductor. He was, up to this time, temperate and regular in all his habits, using no spirits except beer at long intervals. A few months after his promotion to conductor, his train ran down an embankment and was wrecked. Many lives were lost, and he was

* Read at the meeting of the New York Medico-Legal Society, November 2, 1881. Slightly abridged.

greatly excited, fearing the censure of the company and the public, remaining at the scene of the accident over twenty hours without rest or food. He then went home and drank spirits to profound intoxication, remaining in bed two days before he went to work again. From this time he began to use brandy, and occasionally was intoxicated at home at night. Two years after he complained of restlessness and inability to sleep at night; for this, bitters were prescribed, which brought relief. His disposition began to change, and he became more excitable and impatient of opposition. A year or more after he began to drink regularly when the work of the day was over, and by nine or ten in the evening was heavy and stupid from the effects of spirits. He was very exact and methodical in all his habits, drinking beer through the day, and never varying the routine of his life or work from any cause. When thirty-six years old he complained of blanks of memory, or periods in which he could not remember, terminating suddenly, leaving him in some strange position with all the past a blank. His usual habit was to drink in the evening, either at home or at the club, come home always at ten o'clock and retire, get up next morning at four, and take his train a little later. These blanks would come on in the evening and break up at some point on the road the next day; or they would last until late in the afternoon, on his return trip. He would then show much anxiety to know what had taken place in the meantime, fearing he had made some mistake, and inquiring minutely of his wife or some intimate friends. These blanks increased, or were noted by his brother-in-law, a physician. He tried to break up the use of stimulants, but failed, saying he would become insane if he stopped; then he diminished the quantity, but always came back to the usual amount, which was followed by more or less stupor at night. Both his wife and brother-in-law noted these trance states, and fully verified his statements of no recollection of events. For over three years these blanks continued, sometimes every week, then at longer intervals, but steadily increasing in duration, and becoming more prominent in the heavy, stupid air and manner of doing business. He resigned and spent a year on the farm, using less alcohol, and recovering rapidly. He is now in business, and has had no blanks for two years; but at times, after he has drank two or more glasses of beer, his memory is confused for an hour or longer.

The character of the trance state in this case was markedly automatic, the patient doing that which he had been accustomed to day after day. The inebriety dated from the profound excitement of the accident where he supposed he would be blamed. For what reason he became intoxicated at this time was probably unknown to himself. In the trance state his mind acted along the usual channels, without any evidence of its suspended condition; but when this paralysis lifted, he manifested weakness, embarrassment, and alarm at the danger he was in. His fears of doing some extraordinary act, or committing violence in this state, was founded on a knowledge of some inner impulses, which he did not reveal. When free from alcohol his mind exhibited evidence of failure in the irritability and changed disposition. These trance states were purely automatic, and yet they indicated a half-conscious realization of his uncertain state, in the little cautions manifested. His inclination to begin the conversation or answer some question, which had been asked many hours before, showed the reality of the blank, although his manner gave but little evidence of it. I am convinced that many similar cases will be found among those who are pursuing an exhausting, monotonous work. A steamboat pilot informed me that, when worn out from loss of sleep, if he drank a glass or more of brandy, all memory of the time and place would vanish; and some hours after he would recover, finding that he had remained at his post, but could not tell what had happened in this blank. The captain of the boat doubted this, for the reason that he seemed in no way different, only less talkative. A skilled mechanic consulted me for similar blanks which followed excess in the use of spirits, during which he attended a certain dangerous machine, performing all the duties requiring skill and judgment, and yet he could not remember anything which had taken place for hours. He would awake when the machine stopped for the night. When the machine was kept in motion late one night, his blank continued until it stopped. These blanks were trance states following periods of severe drinking, and in many respects like the case we have detailed at length. A house-painter who is an inebriate will paint for hours in the most dangerous positions, while in these trance states, then come down, recover his senses, and wonder how he could have done it without falling.

I have gathered the histories of a number of similar cases, in which, during the trance state, the mind acted as before, with the same discretion and judgment. They are all of them following some methodical work, without change or variation, from day to day; also the alcohol is taken with regularity, and is unattended with any symptoms of intoxication. One of these cases is a grocer, who for hours has a perfect blank in his work, but keeps everything on paper, and thus is able to know what he has done. A second is a clergyman, who, after a few glasses of beer on Sunday morning, has no recollection until night of anything which may have followed. A third is a travelling man for a boot and shoe house, who drinks with every customer; at certain times in his trip he has blanks of one or two days, during which he does business, and has no memory of what has happened. An engineer would attend to his duties in this trance state for hours without giving any evidence of his condition, except general abstractedness of manner. He would show coolness and judgment, the same as if he fully realized his surroundings, and have no memory after. In all these cases there is a similar condition in the automatic state, showing that the mind may go on irrespective of the memory, in certain directions, under the influence of inebriate blanks of many hours, and yet the person attends to his work without knowing what he is doing.

CASE II.—*Trance following Inebriety of Emotional Character.*—A physician came under my care, fifty-one years old, with a history of insanity and phthisis in several members of his family for two generations back. He was educated at Harvard, in both the literary and medical departments, married at twenty-four, and settled in a large manufacturing town. He soon built up an extensive practice, and worked incessantly for many years. When about forty years of age, he suffered from depression and continuous melancholy, following the death of his parents and two of his children. At this time he began to use alcohol as a stimulant when worn out and after a hard day's work. This increased with his labor, and at times he drank regularly, then the amount would be diminished. He was never intoxi-

cated, and yet for weeks he would be under the influence of alcohol all the time. After prolonged overwork and lack of rest, he would fall into a paroxysm of crying before retiring, condemn himself for drinking, saying he would soon die, and then fall asleep, awaking the next morning with no memory of it. These emotional paroxysms would occur every week, and only disappear when he became less exhausted or was rested. All his life he had been a noted skeptic and doubter, never entering a church, but continuously sneering at all religious truth and church organizations. On one occasion, during a season of overwork, followed by the usual excessive use of alcohol, while passing a church where a revival was in progress, he went in, and was soon interested, going forward for prayers, then began to pray and exhort, manifesting great eloquence and enthusiasm. The church-people were overjoyed at his sudden conversion and change of life, but did not discover anything unusual in his manner or words. He went home in a happy frame of mind, singing and praying, went to sleep, and the next morning had no knowledge or recollection of any of these scenes. When informed, he was mortified, and avoided all contact with church-people, going away for a week, for fear his disgrace would be known. Within a year, on several occasions he repeated his first performance. The sound of church-bells and music at night, when he was driving out after having drank freely of alcohol, seemed to throw him into a trance state, during which this strange impulse came on. Finally he became alarmed and went abroad; but, as he used wine freely, these trance states continued at long intervals, and were indicated by paroxysms of prayer and sorrow that he was not better, and resolves to live as he should. After a year of travelling he returned and resumed business, taking a partner, who went with him at night, and watched over him continuously; but still the trance states appeared. He still used alcohol, but could not stop, fearing that he would die without it. He then retired and consulted me. These trance states were, in his opinion, drunken fits, which he wished to be free from. But, like nearly every inebriate, he was confident he could be a moderate drinker, and never be the worse for the use of alcohol. He talked rationally on other matters, and was suffering from rheumatism and general debility. A few weeks' treatment was followed by restoration, after which he went west to live on a farm. A year after he had, in a great measure, recovered.

The marked neurotic inheritance was the favoring soil from which inebriety would naturally follow, depending on any exciting cause that was brought to bear upon it. In this case, the exhaustion of overwork and the mental shock from grief reacted readily into inebriety. This continued for a long time, until the trance state came on. This was at first a mere emotional outburst, manifested in religious feelings; then from circumstances developed into the strange religious interest of short duration, which was utterly a blank to him. The emotional fear of death was present in all these cases, but on no occasion did his friends at the churches have any suspicion of his real state. The knowledge of these scenes from the statements of friends plunged him into deeper melancholy and remorse. His mind was full of alarm at the prospect of insanity, and yet he could not stop. These trances pointed clearly to the failure of the mind and a degree of mental irresponsibility which was not clearly recognized. The line of action was that to which the brain was unaccustomed, and required the play of a new set of faculties. In the first case, the brain in the trance state simply acted along its usual course. In this case a new path was followed. In both an automatic condition was present—one guided by the experience of the past, the other acting from inner impulses in new channels. The same condition is often noted in chronic inebriates, who, after a certain stage of excess in the use of spirit, will exhibit a remarkable spirit of emotional excitement to reform others or protect them from injury or wrong. The strange mental acts and desires at this time are nothing but trance states, in which some of the faculties are suspended, and others are alive and active. The gospel temperance meetings, where the excitement is intense, are excellent places to study this trance state. Men in different stages of alcoholic excess will come forward and sign the pledge and manifest great earnestness, and yet next morning be utterly oblivious to everything done. I have seen many inebriates just this side of stupor and muscular paralysis attracted to these gospel meetings by some means, and become the most enthusiastic temperance men, sign the pledge, and describe their past degradation with evident satisfaction, and close with the wildest assertions and promises for the future. The meetings of Moody and Murphy brought out many very curious illustrations of this phase of inebriety. Thoughtful men often wondered why the same men who were so enthusiastic did not appear more than once or twice at these gatherings. On inquiry, it was found that they had fallen, or gone back, when, in reality, this was a trance state, from which, on recovering, they did not return, because they could not realize the position which had been taken. A United States senator, who was an inebriate, appeared at one of these meetings, and made a solemn pledge not to drink again; the next day he denied it, and never believed or acknowledged that it was true. I have found many persons who join the temperance ranks in this state, when, on finding what they have done, make an honest effort to carry it out. Others are ashamed, and avoid all such influences in the future. The temperance leader never stops to question the strange inconsistency of men who are so positive and earnest in their reformation, then suddenly grow indifferent. To him this is only an evil heart; but to the closer observer it is simply the trance state indicating a degree of degeneracy needing medical rather than spiritual care. I conclude from this that inebriates brought suddenly into conditions of much excitement fall into this state, and are moved by circumstances and surroundings to which they are really oblivious. This state may appear as a simple impulse, or grow into a fixed delusion; as in the case of an inebriate who signed the pledge, went home, and because his brother did not approve of this action, assaulted him with great violence, attempting to force him to believe in it. Often men who sign the pledge in this state suddenly manifest a mania for public speaking in the temperance ranks, and go on for weeks, always drinking in secret, and more or less oblivious to their real condition. In one case, a man who had signed the pledge was for many weeks both drinking and speaking, creating intense excitement everywhere, then recovered, with no connected memory of it. I am firmly confident that this trance state is not only full of danger from impulses of all kinds, but is the fertile soil for delusions which linger long after the origin of them is forgotten. Two patients of mine, who had been sober for four months, both

drank freely, and then went to a gospel temperance meeting. Both went forward, and soon became very warm in their religious feelings. The next day they had no recollection of what had happened, or that they had attended such a meeting; but both affirmed that only prayer could save inebriates, and when asked where they received this impression could not tell. Their history before this event showed that they did not entertain it then, and that it was impressed on them during this trance state; but all the other circumstances were forgotten. It may be stated as a fact that in all cases where religious emotion is constantly appealed to as an element of cure, the patient is on the border of the trance state; and, furthermore, any system of treatment which depends exclusively on the religious element cannot build up healthy tissue or restore defective brain-force.

Case III. is presented to show the prominence of the sexual instinct during the trance state.

A farmer, aged forty-eight, whose parents were eccentric and feeble-minded and had lived away from society, and worked hard a long life-time. When about twenty-six years old the lady to whom he was engaged to be married died suddenly, causing great grief and gloom. Both parents dying soon after, a deep melancholy followed, during which he became more secluded, never leaving the farm unless on business. For many years he lived very retired; when any one called on him he was pleased, and talked cheerfully, but never returned such calls. He seemed to take pleasure in history and spent his leisure reading, never visiting or attending lectures or meetings of any kind. At thirty-nine his sister who kept house for him died, and soon after he was noticed to visit a neighboring town, and buy a jug of whiskey. This was repeated regularly every few weeks at first, then at shorter intervals. No one saw him use stimulants, and he never seemed different from the effects, only more solitary and reserved in his manner. At this time he worked hard, was prosperous, and apparently in good health, manifested excellent judgment, would go to his room at dark, and would not be seen until next morning. The amount of spirits consumed reached a gallon a week, and in the harvest season nearly double; when one day he broke off work abruptly, dressed up and drove away to a neighbor's, asking to see an unmarried lady. He explained his presence as a mere social call, that he had been secluded, but now he was going to be social and visit his friends often. His manner was reserved but polite, and his conversation was clear and sensible. The next week he made other calls on young ladies in the neighborhood, talking very pleasantly a few moments, then going away, thanking them for the invitation to call again. These visits were perfect blanks to him; he would awake next morning and remember nothing of what had taken place after a certain moment in the field or at the house, and wonder greatly how he had employed his time. These blanks continued for several years and were all substantially the same, limited to short calls on different ladies for miles around. He was more secluded than ever in the intervals, refusing to see persons who returned these calls. Coming under my notice, I found him suffering from dyspepsia and many of the usual symptoms following the use of alcohol. He thought he was intoxicated during these blanks, and claimed that he used alcohol to prevent consumption. He was reserved, but seemed to have no fixed opinions about his case, or desire to diminish the use of alcohol. His memory was defective, and he could not work regularly on the farm. He would not consent to anything being done, and two years later he died from gangrene following a broken leg.

The neurotic inheritance and depression following the loss of friends found a natural relief in alcohol, and he became a secret inebriate. The trance state was manifest, after a period of prolonged excess and hard work, in amorous impulses to seek the society of ladies. An extreme caution seemed to be present, holding him from making more than a formal call, and not to visit the same place more than once. Nothing but the unusual character of the call was in any way noticeable. At home the abruptness of leaving business and other important duties was a hint of the change of mind and loss of consciousness. When informed what he had done he seemed more dejected than ever, and became more adverse to society or meeting any one. This trance state gave vent to his latent sexual impulses, which for a time guided his mind. Had he committed an assault at this time, no general evidence in defence relating to his conduct would have indicated more than unusual acts, for which he gave general good reasons at the time in his desire to change his life, and when this trance state had passed away all knowledge of these events would have been denied. No ordinary observation of persons who saw him in this state could have imagined his real condition. I think it will be found that many of the unusual sexual crimes committed by inebriates were done in this trance state, where the higher faculties were arrested, and the animal instincts were left free to guide and suggest. The extraordinary conduct of previously moral men who are inebriates can only be explained by this trance state. When sexual crime follows inebriety it may be either a mere automatic action of a low moral condition, built up and fostered by low thoughts and actions, or the expression of a disturbed function which bursts out into an impulse that is dominant for a time. In the former case some plan or premeditation may seem to be present, because the line of conduct has been outlined in actions and thoughts that have left an impression on the brain. In the latter it is often paroxysmal without plan or purpose, simply the explosion of an impulse which the disorganized brain is powerless to resist. The following cases are given to indicate the prevalence of these trance states in inebriety. I have gathered the history of each one, but merely give an outline for want of space. An inebriate clergyman committed a rape under the most extraordinary circumstances, and asserted that he had no memory of it: the circumstances bore out his statement. A middle-aged business man of excellent character assaulted an old woman. A lawyer of reputation planned the abduction of a lady he was going to marry. A man of standing, and happy in his domestic relations, married a notorious woman, although having a wife and large family. Each of these cases had no memory whatever of the occurrence, and all the circumstances were so unusual, and at variance with previous conduct, as to confirm their statements; and yet they were all punished, and the defence of unconsciousness and irresponsibility was considered weak. No medical study was made of these cases, and the excess in the use of spirits was mentioned as only incidental to the case. The apparent realization of all the circumstances was the point insisted upon in the measure of punishment.

Case IV. was a lawyer of eminence, whose ances-

tors and family had all died of consumption. He was a nervous, passionate man, wealthy, of brilliant talents; ambitious, and industrious; also a devout, conscientious man, and very temperate in all things but eating. After a severe attack of typhoid fever, he began to use whiskey at meals. Three years later he used it both at the table and at night before sleeping. His life was more or less irregular, and he complained of exhaustion and inability to sleep. After a long campaign of speaking, and great irregularity of living, during which he drank constantly large quantities of whiskey, he suddenly called for paper, wrote a will, affirmed that he was going to die, made a full disposition of his property, and, after a night's rest, awoke with no memory of anything which had occurred. A week after he had another paroxysm of melancholy, wrote another will and arranged for death, and awoke a few hours after with all these scenes a blank. During the time of this trance he was perfectly calm and seemed in no way different, reasoned clearly on all matters, and by no word or action betrayed his real state. For two years he remained about the same, having many of these blanks, always attended with the same mental phases and apparent full consciousness; then they changed into suicidal impulses, in which he wished to have his wife die with him. He reasoned very calmly and correctly on this matter, but followed the advice of his friends. The next day he was greatly alarmed when informed of what had happened. Another trance state followed, in which the suicidal impulse took on the form of intense suspicion of the unfaithfulness of his wife. A friend of his took down an elaborate statement of his wrongs; he then made another will, left an explanatory note to be printed in the papers, and finally was persuaded to sleep, after which he awoke, and all the past, as before, was a blank. The friend who wrote this statement was a lawyer, who said that beyond the extraordinary nature of these papers, nothing could be noted of the real condition of the patient. He could not in any way detect mental unsoundness. On another occasion he purchased pistols and a knife, when his friends put him in the care of a lunacy specialist, who called this epilepsy. Two months later he came under my care, and was delirious from the removal of the spirits for two days, then made a slow recovery, and is to-day at a water-cure, improving. The trance states have disappeared, but his mind and body are both feeble.

The inebriety began with the use of spirits after the fever, and the trance state was marked by emotional disturbance and conviction of speedy death. This was but the suggestion of the general exhaustion of the system, and the desire to arrange his property was the usual caution of a business man. The fact of having written his will never remained on his memory, and he always urged to have it written when in this state, even when other copies were exhibited to him. When speaking these blanks came on, but excepting that he had no recollection of anything after a certain time, no one could have realized it. As he grew more exhausted, suicidal impressions started up. These were checked by the interposition of friends. Had he kept these impulses to himself, or not been influenced by friends, they would have developed into a tragedy. He was drifting into a dangerous mental condition, in which impulses of every description were likely to take possession of and control his actions. Had he killed his wife at this time, or any one, no reasonable defence could have been urged that would have been intelligent to a judge or jury, and yet he was in a condition of irresponsibility without doubt. I have verified this condition in the following cases: A retired merchant, while drinking, assaulted a stranger who was attending to other business; he had no consciousness of the act, and at the time said that this man was an enemy, who had deceived him long ago. The assault was cool and devoid of all excitement, and justified at the time by the above reasons, urged with a great show of candor. An inebriate in a large business made the most extraordinary purchases of goods, which he could not remember the next day. A cautious banker, after a season of drinking, invested a large trust fund in Wall Street, and lost it all, without any memory of it after. A very kind, affectionate husband, who was an inebriate, began divorce proceedings while drinking; two days later he was astonished to realize what he had done, all the past being a blank to him. George D. Prentice, the poet and orator, was advertised, and had prepared to deliver a lecture on a certain subject. When the time came he repeated an entirely different lecture, without any knowledge of it; he could not believe it until he read a full report in the next morning's paper. This was a trance state, in which the mind swung into an accustomed channel, and could not be brought back to the subject intended.

The following cases are noted for the prominence of the criminal impulse. I have studied them to bring out the trance condition and the character of the criminal impulse, with some of the varied possibilities of crime which may spring from it.

Case I.—I was called to determine the condition of a man repeatedly convicted and punished for horse-stealing. He was fifty-one years old, a hackman by occupation. His father was a weak-minded man, and his mother died in an insane asylum. At twenty he entered the army, and suffered great hardship as a prisoner. He was an invalid for two years after the war, from malaria, chronic diarrhœa, and rheumatism. At thirty he was employed in a livery stable, and was a moderate beer-drinker. A few years after he was a partner in the business, and was considered honest and a very correct business man. His habits were regular, and he was very fond of horses and driving. About this time he married, and a few months later was noticed to be using spirits to excess at night. No special effects were noticed, except stupor and heaviness, and sometimes extravagant conversation; all his business matters were carefully carried on as usual. One day he walked out, after drinking large quantities of spirits, and unhitched a fine horse in front of a strange residence, and drove about for an hour, bringing the horse to his own stable; and the next day he had no recollection of it. A few weeks later he drove off another horse which he found standing in the street, and put it up in his stable, without any memory of the event. This was with difficulty explained to the owner, and was a great mystery to the man why he should do it. The third event of this kind was driving away a team of horses which had been left in a shed, and after going about for an hour or more offering to sell them at his stable. He was in no way different, talked and acted as usual, said he had bought the team from a stranger and given his check for it, and went into a detailed statement of its merits and excellencies. Except a strong odor of whiskey, he could not be supposed to be under the influence of alcohol. The next day all this was a blank. When told what he had said he could not believe it. Later, he was arrested, and the act was settled only

after much trouble. A year after another similar event, only more aggravated, happened, during which he sold the horse, and appeared to be guilty from his actions; but when arrested his mind returned, and all was a perfect blank. Another event occurred the same year, in which he went about with the owner, showing great interest to discover the horse, when he had placed him in a stable in a neighboring town. He was arrested, and after a long legal contest barely escaped punishment. He was ruined financially, and from this time drank more. Within a few months he was found driving a valuable horse up and down before the owner's house, testing its speed, and asserting it was his own. For this he served one year in prison; the defence of want of memory or knowledge of these scenes was treated with contempt by the court. On another occasion he took a horse, sold it, and went about with the owner for two days trying to find it. He had no memory of anything which had taken place, and was sincere and anxious to help the owner get his property. When it appeared that he was the guilty one he was astonished beyond measure. From this time he went repeatedly to prison, having stolen horses on many occasions, and always after drinking, and in a condition in which he claimed to have no memory of it whatever. Sometimes he showed some degree of cunning in the concealment of horses; at other times he was bold and reckless as to the consequences of being seen. In every case there was a certain purposeless character and absence of motive, other than the mere pleasure of riding behind or driving a good horse. I found him full of delusions of persecutions, and intensely suspicious of others. His memory of events was defective, and he could give no reason for stealing, having no memory of such acts. He drank spirits whenever he could get it, but was never stupid or wild from the effects of excess; but would, after a day's excess, awake, and have no memory of what had happened. To his friends, who had watched him carefully during these trance states, he was more reserved and silent, or impulsive and laughing loudly at times; otherwise he was rational, and seemed fully aware of what he was doing. I pronounced him an inebriate, and irresponsible as to the nature and character of his acts; but he was found guilty and sentenced to prison, where he died a few months later of phthisis.

The inebriety in this case coming from physical causes was marked by a long prodroma before the trance state appeared. The purposeless character of the crime, and the lack of the usual caution manifested by this class of thieves, confirmed the statement of no recollection of it. He could have no special motive to steal when he had so many horses of his own, and when he had stolen he did not seem to use the money he received, or regard it as a gain. He seemed governed by a mere impulse to drive a good horse, never stealing a poor one, and always doing it in an automatic manner, which varied but little from time to time. His previous good conduct and the unusual character of the crime made no difference in the judgment of the court, and he was sentenced over and over again. No one ever thought it possible that he could not realize the real nature of his acts. The following are similar cases which have come under my notice: A teller in a bank, who was a secret inebriate, after a paroxysm of drinking forged a note and put the money in his pocket. The next day he was amazed at the presence of this money, not knowing where it came from. When his guilt was discovered he had no recollection of the circumstance, or reason for it. He was punished, notwithstanding the unusual character of the act, and his defence of no recollection of it.

A rich brewer, after a periodical paroxysm of drinking, would alter his signatures on checks, and refuse to pay drafts. He would have no recollection of these events the next day, and after being convinced of their genuineness, would pay readily.

Another brewer in these trance states, after drinking, would diminish the wages of all his workmen fifty per cent., and if the trance continued long enough a strike would follow. Then he would recover, and all would be reinstated again—he all the time wondering why he had done this, not recollecting anything of it. This has happened a number of times, and is now distinguished by the sudden impulse to cut down the wages.

A farmer of the highest respectability is now serving a life sentence for manslaughter, committed (after drinking spirits to excess) on a man unknown to him, and for no reason or motive. The judge charged that his reasonable conduct up to the time of the homicide, and his appearance of full knowledge of all the surroundings and the consequence of his acts, was strong evidence of his sanity, and that no proof of his inebriety or want of recollection of the homicide should be considered any defence, or by any possible way lessen the responsibility of his crime.

An inebriate of wealth suddenly fired his buildings, and awoke when they were burned down, offering a large reward for the incendiary. When it was traced to him he was amazed, and reformed from that time.

All these cases were that of trance, with the impulse to crime that developed in different ways. I am inclined to believe that some crimes have begun in this state, then, from fear or other conditions, suddenly checked, with the mind partly conscious of the nature and results of the act. Undoubtedly there may be present a strong element of insanity associated with this trance state in crime, still, not distinct enough to be recognized by court or jury. Epilepsy may appear along this line, and be so mixed up with both insanity and inebriety as to make recognition still more difficult. The practical point to be observed is that all such cases must be measured by the facts of their own personal history, thoroughly studied and justly understood.

Case II.—Was a manufacturer, forty-nine years old, who had used alcohol freely at meals for five years. His ancestors were inebriates, and he had begun to use spirits from some supposed debility, until he was obliged to continue them every day. He was very affectionate and generous to his wife and family, and never betrayed any anger or displeasure at their conduct. Suddenly, after taking too much spirits, he became very passionate and offered violence to his wife; her tears roused him from his condition, and he was greatly distressed at his conduct, which was unaccountable to him. He consulted physicians and was treated for months for some brain malady. Then another blank of memory, in which he started the most slanderous stories about his wife staying at a hotel. His conduct was consistent with his stories, and his manner was in no way unusual. On recovery he was again chagrined, and did not believe he had said what was represented to him by others. These blanks, attended by violence to his furniture or his wife increased, and were not noticeable for any other unusual insane conduct, which he fully justified at the time, and always ap-

peared cool and calculating. When friends called during these periods he would reason with great calmness, and be perfectly self-possessed, saying that his head was heavy and he was not well, but would be so next day. He went to Europe and visited the hot springs, with no benefit. Finally he went to an insane asylum and relapsed there, injuring an attendant, but in a way and manner so perfectly cool and free from excitement that the superintendent thought it evidence of a sane mind, and doubted all his statements, discharging him as malicious. I advised him to go under the care of a physician, and he is now free from these trances, and has taken no spirits for many months.

The general history of this case is exceedingly suggestive. The inebriety was followed by a distinct trance condition, with an unusual course of action, utterly at variance with his previous character and habits. The suspicion and violence grew into a dangerous impulse. This always followed after an excessive use of alcohol, and was not attended by any symptoms except the delusion of wrong in his wife, and the desire to right it by violent measures. The passionate violence at these times was of short duration, and the blanks lasted from a few hours to two or more days. His appearance gave no hint of his unconscious condition, and his reasons for violent acts were in a measure sane. He would have committed a fatal assault had a favorable opportunity occurred, and only by the caution of his wife and friends was this avoided. Only a minute study of all the circumstances and history of the case would have indicated the mental instability which was present, and yet he would have received the full measure of punishment at the hands of any court or jury without such study. The case illustrates what in all probability takes place every day in this country, especially in the sudden, purposeless crime committed by inebriates. These cases fill the newspapers, and astonish both courts and juries, who are puzzled to find a motive for the crime, or to attribute it to insanity as described by the text-books, or defined by experts. Sometimes these cases (where the suspicion of irresponsibility is present) are defended, on some strained theory of insanity, whose obscurity confuses the courts, and is criticised and ridiculed by non-experts and ignorant lawyers. These cases are not studied intelligently, and the true theory of their condition is unknown. Two cases will illustrate the every-day experience of courts all over the country. Some man, an inebriate, of low moral nature (which is always an evidence of defective brain organization), comes home, after excess from alcohol, not intoxicated, and in an altercation kills his wife, or some one who may be drawn into the circle accidentally. He is arrested, and has no memory of the event; no study is made of his case; only a few facts of the crime come out prominent. If he has money the defence is technically unnatural, and of course fails; he is punished. The second case is one where previous good character, except excess in the use of spirits, is prominent. He commits a homicide or some strange crime under circumstances that are inadequate to explain or account for it; denies all recollection of it afterward, and the defence must resort to some specious reasoning and theories, or work on the sympathies of the jury. The judge is indignant at what seems to him efforts to defeat justice, and charges strongly against the prisoner; conviction follows; his counsel are sure of some mental defect, and yet they cannot make it clear to either court or jury. If the crime is of petty character, the punishment precipitates him into incurable conditions, and the object of legal measures to prevent and check crime is defeated. The theological notions of the nature and character of inebriety, upon which legal decisions are based, are active causes in developing incurables of this class. One-third of the business of the courts in all our large cities consists of administering what is termed justice to inebriates, but what is literally means which make their recovery more and more impossible. Thus, crime following inebriety, and inebriety itself, are punished, with no effort to study the causes or reach down to understand the physical conditions present. The result is that both Church and State in their ignorant measures to check inebriety are not only increasing its growth, but preparing the soil for its more rapid development.

Hundreds of cases can be selected from the records of courts and prisons equally as prominent as those I have presented; all conspicuous for crime committed after and during excess in the use of alcohol; all denying any recollection of the event, and all the circumstances of want of motive and purpose confirming their statements. Yet in all these cases there has been no medical study to understand the mental condition which would develop into such acts. Assumptions of perfect sanity and capacity to reason clearly have governed the decisions in these cases. So long as the inebriate was not stupid, or wildly delirious, he is supposed to be fully cognizant of all his acts; it is considered a vice and punishable up to a certain line, and beyond that a doubt might be entertained. This is the same spirit of superstition which punished witches and believed in demoniacal possessions, ignoring all physical causes, and is clearly outlined in the late charge of an eminent judge, as follows:

"Intoxication from excess of alcohol is no defence for crime, and cannot in any way lessen the measure of responsibility."

If inebriety is only a voluntary spiritual state, this is good law, probably; but if it is an involuntary physical condition, a reform is demanded in both theory and practice.

I pause at this point to arrange some of the conclusions which stand out prominently from the facts stated. The great obstacle apparent in the medico-legal recognition of this trance state is the confusion of opinion as to the disease of inebriety. It is a remarkable fact that, notwithstanding the great advances made in the field of mental sciences, and the increasing prominence of inebriety in its effects in every community, the same opinions prevail to-day which were taught centuries ago. Insanity has emerged from the superstitions of religious teachers, but inebriety is still invested with murky theories of vice, sin, and punishment. All studies of its nature and causation have been made from the moral side alone. As a natural result the application of means and measures for the care and control of inebriety, based on such views, have utterly failed. Practically no other result can be expected until the entire subject is studied from a scientific standpoint, above the dogmas of theologians and reformed inebriates. The world moves, and no measures for the benefit of society or the elevation of the race will succeed, unless founded on the truths of nature, and along the line of its eternal laws. The inebriate in this trance state is a mere automaton in motion, either moving along certain fixed lines of conduct, or acting in obedience to unknown forces, which may change or

vary any moment. Some governing centre has suspended, and all consciousness of time and the relation of events has stopped. Changing thoughts and impulses, the suggestion of a disturbed organ, or the impression of a thought or desire coming from the past, may suddenly concentrate into action, irrespective of consequences. Both subjective and objective states, influenced by conditions of health and brain power, may develop into deeds that are practically unknown and unrecorded by the higher brain-centres.

The phenomena of this state divides into two forms. One, probably the most common, in which the mind moves along certain familiar lines of action, and follows some purpose which has been previously fixed, all of which appears natural and reasonable; as, for instance, the conductor pursuing his every-day work, or the banker who attends to all his usual business, unconscious of what takes place. Second, a new line of thought and action appears, unusual and foreign to his every-day life. Often impulsive and inconsistent, he is yet seemingly conscious of his failings, and if questioned may give reasons that seem to justify his conduct. As, for instance, the physician who attended the prayer-meeting, or the lawyer who wrote a will in every trance state, etc. In both of these forms sudden changes from one state to another may follow. Emotional disturbances may precede this state, or may appear coincidently with it. The senses are blunted or enfeebled, or they may be intensified in certain directions. Except this, perhaps, there is little evidence of unconsciousness, and if the impulse is criminal it may appear without premonition, like a flash of light, and disappear with equal suddenness. Legally, the first question is the inebriety of the patient. On this point the inference will be clear if the person has used alcohol at intervals or continuously to intoxication. The degree of this excess need not be stupor or delirium, but whenever it is marked by changes of intellect, manner, temper, disposition, habits, and character, inebriety is present. Next, the presence of the trance state, which may be shown from the statement of the patient, and all the circumstances of this state, with a history of the case.

*First.*—The statement of the patient that he did not remember the act may be made to shield him from its legal consequences, or save his reputation. The general principle here is that the use of alcohol invariably impairs the memory, and that confusion of mind and disturbed will-power is a pathological result from the same cause; hence there is always a physiological possibility of the correctness of the statement.

*Second.*—The general character of his conduct during this state will bear out his claim of trance. His general abstractedness of manner, or his strange, inconsistent actions, unusual in motive and object, united with no apparent recognition of the surroundings, may be taken as evidence. The farmer who went about visiting was strangely inconsistent in conduct; the engineer was very abstract and reserved in his manners, etc.

*Third.*—The range of the mind, and the general vigor and health displayed, will give some indications of the consciousness of his acts in this state. The sudden change from frankness to reserve, or from confidence to suspicion, or the presence of emotional excitement in little things, melancholy or hilarity, the rapid change of the mind from one extreme to another, are also evidences. The physician, from a sceptic, became a pious man in this state; the manufacturer became violent to his wife, whom he loved very dearly, etc.

*Fourth.*—If crime is committed, or any conduct which perils the good order of the community, a careful study will bring out the evidence of the mental state present.

As in the case of the hackman, a full history of his stealing was clearly that of a man not realizing the consequences of his acts. Or in the lawyer who wrote his will, and had suicidal impressions, the entire history of these acts pointed to the trance state. Lastly, a general history, which will include inheritance, education, mental capacity, and health, will bring out many factors to determine the case. The patient's acts after coming out of the trance state will also determine its presence. He will manifest an indifference and a change of conduct from that noted in this state. An illustrative case recently under my care was that of a dentist, who in this state was very anxious to make money, although wealthy, but when this condition passed away all his money schemes were forgotten. In another case a man murdered his wife in a trance state, and went about for hours not realizing what he had done, or making any effort to escape. From these and other studies the trance state may be reasonably proven to any court or jury. Then comes the question of responsibility. Clinical facts within the observation of any one will indicate unmistakably that in all cases of inebriety there is a defective brain-power and general perversions of healthy activity. Also, when inebriety is present, the door is open for many and complex nervous disorders, which often complicate and make the inebriety more uncertain and doubtful. Hence, when inebriety is proven to exist, the responsibility of the patient for his acts is lessened—he is not of sound mind. When the trance state is determined, the actual responsibility or cognizance of right and wrong is suspended, and the patient is a mental waif, without compass or chart. No evidence of premeditation or apparent judgment in his actions can alter this fact. Any course of action marked by this may come from some impression laid up in the past, which, when conscious reason is withdrawn, takes on form and semblance. The real condition of the mind in this state is more or less concealed. Nothing less than a thorough medical study of every case, by competent men, can determine the measure of responsibility. Such a study must be made from a physical point, based on the facts, for nothing can be a greater injustice to both the patient and the community than to condemn and punish without a knowledge of all the conditions and circumstances. The object of the law to protect the rights and interests of individuals is defeated where its enforcement precipitates the victims into more hopeless conditions. Inebriety in any of its forms may be no excuse for crime in law, but it can never, in any case, be an excuse for punishment which destroys the victim. The time has come to lay aside the legal barbarisms, relating to inebriety of the past, founded on superstition and ignorance. The border-lines of sanity and responsibility in inebriety, as laid down by courts, are unsupported by facts and the teachings of science.

Inebriety in all cases must be regarded as a disease, and the patient forced to use the means for recovery. Like the victim of an infectious disease his personal responsibility is increased, and the community with him are bound to make the treatment a necessity.

The following propositions sum up many of the facts mentioned:

*First.*—Inebriety must be recognized as a condition of legal irresponsibility to a certain extent, depending on the character and circumstances of the case, and the general mental integrity displayed.

*Second.*—All unusual acts or crime committed by inebriates, either in a state of partial coma or alleged amnesia, which come under legal recognition, should receive thorough study by competent physicians before the legal responsibility can be determined.

*Third.*—When the trance state is established beyond doubt, he is both legally and practically irresponsible for his acts during this period. And each case should be measured by the facts of its individual history.

*Fourth.*—Inebriety is a disease requiring physical means in the treatment. Society demands of the patient that he use diligence to recover, and so far as he may neglect this, both himself and the community are responsible.

*Fifth.*—It is the duty of the State to provide asylums and encourage private enterprise to furnish the means and appliances for restoration.

*Sixth.*—Lastly, standing on this border-land, and looking back at the monstrous injustice and legal crime that is daily committed in the punishment of inebriates, who are practically insane, I am convinced that the time has come for a revolution of sentiment and practice, in which both the inebriate and the community must be held responsible, not alone for his acts, or the consequences of them, but the causes and conditions which have developed in this way; then the victim will be forced to avail himself of every means for prevention, restoration, and recovery.

---

THE VALUE OF MENTAL TENSION.—A certain degree of tension is indispensable to the easy and healthful discharge of mental functions. Like the national instrument of Scotland, the mind drones wofully and will discourse most dolorous music unless an expansive and resilient force within supplies the basis of quickly responsive action. No good, great, or enduring work can be safely accomplished by brain-force without a reserve of strength sufficient to give buoyancy to the exercise, and, if I may so say, rhythm to the operations of the mind. Working at high pressure may be bad, but working at low pressure is incomparably worse. As a matter of experience, a sense of weariness commonly precedes collapse from "overwork;" not mere bodily or nervous fatigue, but a more or less conscious distaste for the business in hand, or perhaps for some other subject of thought or anxiety which obtrudes itself. It is the offensive or irritating burden that breaks the back. Thoroughly agreeable employment, however engrossing, stimulates the recuperative faculty while it taxes the strength, and the supply of nerve-force seldom falls short of the demand. When a feeling of disgust or weariness is not experienced, this may be because the compelling sense of duty has crushed self out of thought. Nevertheless, if the will is not pleasurably excited, if it rules like a martinet without affection or interest, there is no *verve*, and, like a complex piece of machinery working with friction and heated bearings, the mind wears itself away and a breakdown ensues. — DR. J. MORTIMER GRANVILLE on "Worry," in *Popular Science Monthly* for November.

## SOME CASES THAT DO NOT ILLUSTRATE REFLEX DISTURBANCES FROM GENITAL IRRITATION.

BY C. L. DANA, A.M., M.D.,

PHYSICIAN TO THE CLASS OF NERVOUS DISEASES, NORTHEASTERN DISPENSARY, N. Y.

THE interest excited by Dr. Gray's paper, and the discussion at the meeting of the Neurological Society, November 1st, lead me to ask for the publication of the following cases as pertinent to the question at issue.

The first is that of an infant who was, apparently, a typically good case for the operation for phimosis. He had incontinence of urine and no control over the legs, which were adducted and crossed in the way described by Dr. Sayre. The prepuce was an embodied prayer for amputation, according to all the data given for that operation by the exponents of the reflex doctrines. It was accordingly removed. For six weeks the child was not perceptibly improved. A radical change in diet and medicines was then ordered. In two weeks nearly every bad symptom had disappeared.

The second case illustrates another side of the matter. The patient had had acute anterior poliomyelitis six months before. It had improved rapidly, then not at all, and finally it began to get worse, as shown by increasing lameness, atrophy, irritability of temper, general weakness, and anorexia. The prepuce was long, reddened, and adherent, the orifice was very small, the organ irritable. Yet the child rapidly and steadily improved in all its symptoms, under electricity, massage, nux vomica, and counter-irritation.

I present these cases in full below, because I believe they are types of a very large number, and that their significance was not sufficiently dwelt upon in the discussion of Dr. Gray's paper.

Nearly every male child has a long prepuce, and in would naturally happen that a great many of these are tight, or reddened, or adherent. Yet clinical records fail to show that any great proportion of these children suffer from nervous disturbances of serious character. One would not expect often to get reports of cases like my first, where the operation did no good, nor of cases like the second, where cure results without any attention to the phimosis. Yet I have heard of similar ones, and such cases show us that an irritable prepuce is, as a rule, only one factor in producing the disturbances alleged to be reflex. Children—and especially city children—under five years of age, are not a very healthy class at the best. Half of our mortality is from them, though they make but one-eighth of the population. Ten per cent. die every year, and ten per cent. are sick all the time.* Nearly a fourth die from constitutional diseases, while not more than one-fiftieth die from any nervous diseases except meningitis and convulsions. These latter occur almost equally in male and female; few would ever assign genital irritation as a cause.

One may reasonably expect, therefore, in young children some organic disease or some defect in nutrition to be present, and act more or less permanently in producing the nervous disturbances. And consequently the most rational view seems to be that in the great majority of cases other factors than genital irritation exist to produce the nervous trouble:

* These are approximate figures obtained from a study of the New York City Board of Health reports.

sought to be alleviated. There is little doubt, from the present evidence, that genital and even preputial irritation can *alone*, in rare cases, cause reflex nervous disturbances, perhaps even paralysis. Sometimes this genital irritation may be the chief factor, or again it may take but a small part in the matter; or, other morbid changes may have so affected the nervous system that a slight but constant genital irritation is enough to upset the healthy balance of nervous forces and produce paralysis, convulsions, enuresis, etc.

Whether genital irritation be a sole cause or an exciting cause, or only an aggravating element, the question of treatment is little changed, however. The irritation should be removed. If there were a foreign body on the conjunctiva keeping up a constant disturbance, one would remove it and not think he was displaying any remarkable degree of surgical acuteness. The conditions are, to some extent, analogous in cases of phimosis, with balanitis, etc.

Dr. Gray has done a service in showing so forcibly the other side of this question of reflex irritation: it is that we very rarely, indeed, have a specific cause in an irritable prepuce, or a specific remedy in circumcision.

Case I.—Boy, aged fifteen months; had always been well until two months before, except that he was rather small in size, and had developed slowly. When first seen, the arms and legs were thin, abdomen full, the legs were under little control; he could neither creep nor walk; generally kept the thighs adducted, and the limbs more or less crossed. He was dull and spiritless, and altogether looked rather puny and rickety. Still, the face was full, the appetite and digestion good. He had been weaned at nine months, and the parents reported feeding him on condensed milk, oat-meal, beef-tea, etc.

The patient was brought to me, March 24, 1877, on account of incontinence of urine, which had been getting worse during the previous two months. The child passed water very frequently both day and night, the bladder not seeming able to hold urine long. The urine passed was very light-colored; specific gravity 1004. There was no evidence of cystitis or stone. The prepuce was long, the orifice contracted to the size of a crow-quill; the end was somewhat reddened and inflamed. There was a small cul-de-sac between the glans and the orifice of the prepuce in front of the frenum, where a little urine often remained after micturition. The prepuce was adherent to the glans. The penis was subject to frequent erection, not due to the child's rubbing or irritating it.

The father, who was a very intelligent man, had been a surgical instrument maker, and had read Dr. Sayre's monograph, then but recently published. He was convinced that his child belonged to the class described by Dr. Sayre, and brought him to me to be circumcised. It seemed to be a particularly good case for operation, and I therefore removed the foreskin on March 26th. The wound healed without any trouble.

April 15th.—No change had taken place in any of the symptoms. The child continued to eat and was tolerably comfortable. Belladonna, which had been ordered previously, was discontinued.

April 23d.—No change. Ordered cod-liver oil, iron, hot hip-baths.

May 2d.—No change. Ordered complete change in diet, with larger amounts of food, oil, and lacto-phosphate of lime.

May 20th.—Rapid improvement since last date. Enuresis stopped. The boy from this date went on to rapid recovery, and in a few weeks could use his limbs.

For nearly two years he continued well. He then developed Pott's disease. From this he recovered after a year's treatment with the plaster-jacket.

Case II.—C. L——, aged two; family healthy; was himself healthy and plump until about May, 1881, which was nearly six months before I saw him. The mother says that he was then pushed over and injured by a playmate. Next day had to be put to bed; paraplegia set in, and lasted three weeks. Patient then regained the use of his right leg perfectly, but power in the left returned very slowly. Progress finally stopped; the limb began to grow worse. The boy meanwhile had become nervous, irritable, and had lost his appetite.

October 16th.—First saw the patient. He was plump, but anæmic; could walk, but dragged his left limb. The foot was turned out as in beginning talipes valgus. The left limb was markedly smaller and softer than the right. Electrical contractility slight.

The prepuce was very long, adherent to the glans, red, and inflamed at the end; the orifice extremely small, so that the glans could not be uncovered. The penis was sensitive, the child crying and struggling when it was touched, though this was probably in part from fright. The mother did not wish him to be operated upon. There was no incontinence of urine. The only nervous symptom was the general irritability, which had not characterized him at all six months before.

The patient was put under a treatment of electricity, massage, nux vomica, and counter-irritation to the back. Improvement began at once, and continued uninterruptedly. At date (November 9th) the patient scarcely drags the foot at all; has much more power in the limb; electrical contractility better; appetite returned; nervousness greatly diminished.

The prepuce continues in the same condition. It would doubtless be better if it were removed, but it does not seem to interfere with the progress of the child toward health.

## A TOOTH IN A BRONCHUS FOR FIVE DAYS CAUSES PNEUMONIA—RECOVERY OF THE PATIENT.

By T. R. CHAMBERS, M.D.,
EAST ORANGE, N. J.

Mrs. K——, aged thirty-five; healthy; wife of a farmer.

August 19th.—She had thirteen teeth extracted from the upper jaw at one sitting, by an experienced (?) dentist in New York city. Upon discontinuing the administration of gas (nitrous oxide) she fainted. Then she was seized with severe epigastric pain, urgent dyspnœa, cough, nausea, and prostration. It was several hours before she could be removed to her home in Orange.

August 22d.—The dyspnœa, nausea, and cough continued, and in addition there was severe pain in the left axillary line on a level with the nipples, at which place there was a zone of bronchial breathing and voice, and dulness over a space not larger than a silver dollar. In the neighborhood were mucous râles. This consolidation was preceded for two days by pulmonary congestion. The cough to-day less in frequency and severity. Sputa scanty, serous, and muco-purulent, streaked with blood. Temperature, 102° F.; respiration, 40; pulse, 102.

August 23d.—Temperature, 104° F.; respiration, 38; pulse, 110.

August 24th (sixth day).—At 9 A.M. there was a severe coughing with urgent dyspnœa (the patient says "she thought she would be suffocated"), terminating with a spasm and vomiting, after which relief was obtained. In the matter coughed up and vomited was found a second molar tooth. It was positively certain that it did not come from either jaw at this time, as both had been carefully examined since the illness began. Blood was abundant in the sputa, which was muco-purulent in character. Cough very much easier. The whole lower lobe gave bronchial breathing and voice, with dulness. Temperature, 104° F.; respiration, 44; pulse, 124 (two hours after the coughing struggle).

August 25th (seventh day).—Patient generally easier. Sputa copious and blood-streaked. Temperature, 100.5° F.; respiration, 32, pulse, 100.

August 28th. — Prostration marked. Copious sweats. Blood disappeared from sputa.

September 19th (one month).—Patient up and about. Vesicular respiration returned to lung. Râles abundant.

September 25th.—Patient well, except weak.

A gentleman of large experience in extracting teeth says that, "even when the greatest care is exercised, a tooth will sometimes slip out of the forceps. If it should happen to fall into the throat it will be swallowed. No exercise of skill can prevent this. When it is swallowed it does no harm. If it lodges in the throat—which is a very rare occurrence—it can be thrown out by an emetic." Just so, but in the case cited a whole molar tooth, perfectly sound (heaven forgive the dentist for pulling such a good tooth!), went past the throat, through the glottis to the lung. Here, if it had not been dislodged and coughed out, abscess and almost surely death would have been the result.

Now, where so many teeth are extracted at one sitting, the operator must, of necessity, be expeditious; but it does seem as if there should be time enough to remove entirely from the mouth any tooth or part of a tooth loosened from its bed in the jaw. The person at this time is in a state of induced coma, the sensibility of the larynx is very much less than normal, so that resistance to the entrance of a foreign body past the glottis is likewise diminished.

Thus, it behooves operators to use a care in avoiding this serious accident. Where a patient fails to recover upon discontinuing the administration of gas, every loosened tooth or part of a tooth should be accounted for, and means be employed at once to discover and release the foreign body if it be caught anywhere in the throat or respiratory tract.

THE ELECTRICAL EXHIBITION AT PARIS.—A number of instruments connected with medicine and surgery were shown at this exhibition. New galvanic batteries, invented by Dr. Onimus and Dr. Seure, were displayed. The electrical polyscope of Trouvé was on exhibition; also all the electrical apparatus of the Salpêtrière, including an imposing cabinet that furnished any form of electricity, and a powerful static machine devised by M. Vigoureaux. Dr. Boudet showed a cardiaphone, a sphygmophone, and a myophone; also an electrical diapason for the treatment of pain by mechanical vibrations; and a coil set in a wooden frame and arranged to encircle the head for the electrization of the brain. A prominent characteristic of the medical part of the exhibition was the number and variety of franklinic machines.

# Reports of Hospitals.

## LONDON HOSPITAL, LONDON, ENG.

SERVICE OF DR. STEPHEN MCKENZIE.

(Reported by Wm. J. Belfield, M.D., Chicago.)

### FILARIA SANGUINIS HOMINIS.

THE patient, a robust man, aged twenty-six years, a private in the Royal Artillery, was born and bred in India. Had never suffered any other illness than gonorrhœa. Last spring he landed in Dover, on his first visit to England, in the enjoyment of his usual good health. A few weeks later his urine became bloody and then milky, and has maintained the latter appearance ever since. Upon admission to our hospital, in August, the worms were discovered. Observations taken every three hours soon established the periodicity of their appearance in the blood, first observed by Manson. At midnight there were always from fifty to one hundred in a drop of blood covered by a five-eighths of an inch square cover-glass. The number decreased rapidly until 9 A.M., when few or none were observed. From this hour until 4 or 5 P.M. they were seldom seen, but then regularly reappeared, increasing in number until midnight again. After several weeks' observation, during which this periodicity was constant and uniform, the usual diurnal programme was reversed, the patient sleeping by day, and taking his meals and exercise by night. There occurred at once a serious perturbation among the worms, which now appeared in greatest numbers by day; yet they did not disappear during the night, nor was the crescendo and diminuendo of their numbers so uniform as during the previous mode of life, perhaps in part because his sleep was always more or less disturbed. The usual routine, sleeping at night, has been recently resumed, and the worms have promptly resumed their former hours as well.

The urine has been of milky appearance, 108 to 210 ounces daily; specific gravity 1009 to 1012; alkaline or neutral in reaction, containing one-tenth to one-fourth per cent. (by weight) of albumen, five-tenths to nine-tenths per cent. urea, seven-tenths to one per cent. fat; fibrin, blood-corpuscles, and living filariæ (by day as well as by night); no sugar. Upon standing, large, soft clots are formed; sometimes the coagulum included almost the entire bulk of the urine. These clots were often formed in the bladder, causing great difficulty in micturition. The patient's general health is good. He is quite interested in the appearance and natural history of his parasitic tenantry, and has rendered himself very serviceable at times in counting the worms.

The animals vary from $\frac{1}{70}$ to $\frac{1}{77}$ of an inch in length, and from $\frac{1}{2\times00}$ to $\frac{1}{3\times00}$ in greatest thickness; the average of ten measurements gave $\frac{1}{317}$. They present the usual envelope and structure (or absence of structure) of nematode worms in the undeveloped state. Their movements are at first very active, consisting simply of eel-like contortions, the worms being, of course, incapable of locomotion.

Dr. Mackenzie intends reporting the case in detail to the Pathological Society this winter, in whose proceedings it will doubtless be published.

THE MICHAEL REESE HOSPITAL at Chigago was formally dedicated on October 23d. It is under Jewish management, but is to be non-sectarian.

# Progress of Medical Science.

PERFORATION OF THE BLADDER BY DERMOID CYSTS OF THE OVARY.—Injuries and pathological changes in the cyst-wall occasionally give rise to perforation of the bladder by ovarian tumors, in which case a favorable result is usually observed. Dermoid cysts of the ovary, by reason of their tendency to inflammation and suppuration, are especially prone to perforate into the neighboring organs; and since such cysts have not as yet been discovered in the walls of the bladder, we may with certainty diagnose perforation of this viscus by a dermoid cyst whenever hairs and teeth are evacuated through the urethra. Waelle adds another to the list of such cases. The patient had suffered during a period of five years from dysuria, hæmaturia, and gravel. On exploration of the bladder a foreign body was detected, which, upon extraction, proved to be a tooth. Disinfectant irrigations were ordered, but the patient died shortly afterward with symptoms of acute diffuse peritonitis. At the autopsy a dermoid cyst, as large as a hen's egg and containing a second tooth, was found adherent to the posterior wall of the bladder, there being a distinct communication between the two cavities.—*Centralblatt für Gynäkologie*, August 20, 1881.

TREATMENT OF MALIGNANT PUSTULE.—The results hitherto obtained in the treatment of malignant pustule by cauterization, etc., leave much to be desired. Verneuil (*Progrès Médical*, February 12, 1881) recommends destructive cauterization of the central gangrenous portion, punctate cauterization of the intermediate (vesicular) zone, and parenchymatous injections of iodine into the outermost or œdematous zone. Popper (*Centralblatt für Chirurgie*, August 20, 1881) claims to be able to cure every case of pustula maligna, no matter where situated, within twenty-four hours, if patients present themselves before the stage of systemic infection. His method consists simply in thorough extirpation with the knife, by a circular incision penetrating into the subcutaneous connective tissue beyond the diseased area. The author does not state whether this includes the œdematous zone or not. Should the central slough extend more deeply into muscular tissue, this must also be excised, after which an antiseptic dressing should be applied. It usually requires but a few hours for the swelling surrounding the pustule to subside, and patients are always able to continue their business, excepting, of course, in those cases where general infection has already manifested itself. The author, however, neglects to state what results were obtained in these cases.

ENTERECTOMY.—In a case of strangulated hernia, with gangrene of the intestine, Juillard endeavored, after resecting a loop fifteen centimetres in length, to unite the cut ends by invagination after Jobert's method, but the difference in the calibre of the two portions was so great as to render the procedure impracticable. The ends of the gut were then brought together by four Lembert catgut sutures, applied one centimetre from the margins of the incisions, and equidistant from one another. As each knot was tightened, the lower end of the intestine was folded inward upon itself at this point, and then the corresponding part of the upper end thrust into it. The invagination thus accomplished was then secured by nine additional Lembert's sutures. The case terminated favorably, the bowels moving for the first time on the eighth day.

Juillard recommends the above modification in place of Lembert's plan, as ordinarily practised, for the reason that the sutures in the latter apparently do not hold securely; for in five out of the twenty-five cases with which he is acquainted they gave way. This accident, as far as he knows, has never followed Jobert's method. Despite of the favorable termination in the above case, the author advises secondary resection of the gut in gangrenous hernia. The chief danger in enterectomy is the tearing out of the sutures; this is much more to be apprehended in primary (immediate) than in secondary resections, because in the former the tissues are more friable, the difference in the lumina of the two ends of intestine is greater, and the central portion of the intestine is more distended than in the latter. In all of the five cases in which the sutures had torn through, primary resection had been performed, while out of twelve cases of enterectomy, with subsequent suture for the relief of artifical anus, but two ended fatally, and even in these the sutures had not given way. The best method of procedure, then, in cases of gangrenous hernia, would be to establish an artificial anus, and to close the latter by resection of the gut and suture of the intestine, after a lapse of two or three weeks.—*Centralblatt für Chirurgie*, August 27, 1881.

INSANITY RESULTING FROM DEPRESSED FRACTURE OF THE SKULL CURED BY TREPHINING.—A patient of Dr. Daniel Mollière, suffering from traumatic insanity resulting from a depressed fracture on the left parietal region, presented only vague general symptoms. There was no localized anæsthesia, no paralysis, and no febrile movement. Dr. Mollière, having diagnosticated traumatic insanity due to cerebral irritation from spiculæ of the depressed bone, removed six fragments of bone by means of the trephine, the screw-elevator, a gauge, and a mallet, thus denuding the dura mater. The wound, which was treated by Lister's method, healed in a month. The patient quickly recovered his reason, but evinced a peculiar irritability, and a loquacity comparable to that of slightly intoxicated persons. The symptoms disappeared, however, after a few months, and the patient's functions were thenceforth normally performed.—*Annales et Bulletin de la Société de Médecine de Gand*, May, 1881.

LOCAL TREATMENT OF HAY FEVER.—M. De Budberg, a Swiss observer, draws attention (*British Medical Journal*, July 2, 1881) to a simple, and, as he claims, efficient method of treating this distressing malady. It appears to have been discovered by Helmholtz, and as yet is but little known. The first case was observed by M. De Budberg in an Englishwoman, who had suffered from hay fever for twenty years. The treatment employed consisted of nasal irrigations of a solution of quinine (1 part in 750 of water). This irrigation brought away masses of brownish mucus, in which were found small round yellow corpuscles, of smaller dimensions than the blood-corpuscles. It did not contain either vibrios or bacteria. After two or three douches the patient was perfectly well. The attack was arrested from that time. A solution of chlorate of potash was employed, and no relapse occurred, although the patient frequently passed flowering meadows. Every time that she attempted to suspend the treatment a relapse occurred, which, however, was promptly ameliorated by the use of the douche. M. De Budberg thinks that the yellow corpuscles

found in the nasal mucus of this lady were pollen-corpuscles. The nasal douche freed the mucous membrane from them; hence its curative effect. In cases in which the mucus contained bacteria, Helmholtz's solution of quinine would probably be indispensable. In all cases it is necessary that the douche should be made most carefully, so as to entirely wash out the whole of the nasal mucous membrane. Dr. Blackley, in his excellent monograph, relates that he induced hay fever in his own person by the introduction, on the nasal mucous membrane, of various kinds of pollen. He cites more than sixty different kinds of them—as a rule, graminaceous pollens.

THE USE OF AMMONIA IN PULMONARY DISEASES.—At the meeting of the Royal Belgian Academy of Medicine, April 30, 1881, M. Melsens presented a memoir on the therapeutic applications of ammonia, its salts or its complex compounds, requesting that a committee be appointed to examine into the value of his conclusions relative to this question. M. Melsen's communication discusses the applicability of ammonia and its compounds to diseases of the respiratory organs. He concluded, from the fact that phthisical patients are benefited by inhaling the vapors of carbonate of ammonia emanating from stables, that the continuous and moderate inhalation of that salt would be efficacious in other pulmonary affections. He accordingly made the experiment upon himself during an attack of bronchitis, by wearing, in a bag attached to his shirt, several pieces of ammonic carbonate. Having been completely cured, in a few days, by this treatment, he subsequently employed it in his practice, with uniform good results. He also applies the remedy directly to the respiratory passages, by means of the spray, with equal success.—*Bulletin de l'Académie Royale de Médecine de Belgique*, vol. xv., No. 4.

ACTION OF COFFEE AND SUGAR ON THE STOMACH.—M. Leven has communicated to the Paris Society of Biology some experiments which he has made on this subject on dogs, with the assistance of M. Semerie. The action of coffee on the stomach has been much discussed and variously interpreted; the majority of writers admit that coffee stimulates the circulation and provokes hyperæmia of the gastric mucous membrane, but they have not adduced experimental proof of the fact. The contrary opinion is supported by a certain number of observers, to whom M. Leven has given in his adhesion. He recalls to mind the experiments which he made some years since on caffeine absorbed by frogs, guinea-pigs, and rabbits. It retarded the action of the heart, which, at the same time, became strong; it increased the arterial tension; like the vaso-constrictor agents, it dilated the pupil. Caffeine has even been used in certain cases to replace digitaline, of which it has, to a great extent, the properties, though in a smaller degree. The latest experiments of M. Leven were as follows: he gave to a dog a meal of 200 grammes of meat; he then administered an infusion of 36 grammes of coffee in 150 grammes of water; the animal was then killed, and, at the end of three hours, the stomach still contained 145 grammes of meat, while in the absence of coffee it only contained about one hundred grammes. The abdominal mucous membrane was pale as well on the external surface as in the interior, and the vessels were strongly contracted. It follows, then, that coffee, producing anæmia of the stomach, retards digestion; and, the anæmia repeating itself, ends by bringing on habitual increased congestion of the stomach, which, according to M. Leven, is synonymous with dyspepsia. It is well known, and English physicians have laid great stress upon this point, that the abuse of coffee and tea often brings on gastralgia, dyspepsia, and, at the same time, more or less disturbance of the apparatus of innervation. It is, therefore, necessary precisely to distinguish the local anæmia produced by coffee on the stomach from the more general action exercised by it over the central nervous system, and which has conferred on it the merited qualification of an intellectual drink. In opposition to coffee, sugar is, according to M. Leven, an eminently digestive substance; and he does not fail to order it in certain cases of dyspepsia. He has made the following experiments: He gave to a dog 80 grammes of sugar at the same time as 200 grammes of meat; six hours afterward there was nothing found in the stomach but twenty grammes of undigested meat. The abdominal mucous membrane was red and turgescent, the liver was wholly congested. M. Leven draws this practical lesson from his experiments: that the infusion of coffee should be sufficiently sweetened to stimulate the secretory function, and thus assist digestion.—*British Medical Journal*, July 30, 1881.

RECIPROCAL RELATIONS OF WOUNDS AND MALARIAL FEVER.—The statement is made by M. Verneuil (*Tribune Médicale*), that the malarial dyscrasia may manifest itself in various surgical affections, developed simultaneously with the ordinary rational symptoms of the disease. The author cites local gangrene, lymphangitis, furuncles, carbuncles, erysipelas, and visceral hemorrhages, as among the surgical diseases engendered by the malarial poison. The affections may be of a clearly periodic type, or may recur at irregular intervals. Two classes of cases are cited by M. Verneuil. In the former, the malarial diathesis appears during an old or a recent surgical affection. In the latter, surgical diseases appear spontaneously during the persistence of the malarial dyscrasia. In the latter case, the intercurrent malarial disease, exerting its chief influence on those tissues least capable of resistance, naturally selects the wounded member as the seat of its pathological manifestations. It is therefore here that phlegmonous inflammations, ulcerations, and chronic neuralgias are encountered. "The traumatism," says the author, "creates nothing in the diathesis. It only provokes the apparition of manifestations which the diathesis would have spontaneously produced at another time." The relations of the malarial poison and of traumatism are, however, of a reciprocal nature. If therefore a wounded person is subjected to the exciting cause of the malarial disease, the latter is much more liable to become developed than it would be were the person exposed unwounded. Persons apparently entirely recovered from malarial fever frequently trace relapses to the depressing influence of a surgical injury. Mons. V. concludes his article with the comprehensive statement that "traumatism modifies, recalls, attracts, or awakens malarial manifestations," and makes an inquiry regarding the possible existence of hereditary malarial disease.—*Annales et Bulletin de la Société de Médecine de Gand*, June, 1881.

A REMEDY FOR HICCOUGH.—Dr. M. S. Leslie, of Lexington, Ky., says that the best remedy in ordinary hiccoughs is about twenty-five grains of common table-salt, placed in the mouth and swallowed with a sip of water.

## PROFESSIONAL FEES IN THE LATE PRESIDENT'S CASE.

WITHIN the past few days there has been considerable discussion in the secular press as to the amount to be charged for professional attendance upon the late President Garfield.

As can easily be imagined, various opinions obtain, not only regarding the actual worth of the services rendered, but as to the means to be adopted to secure payment for the same. All sorts of rumors have prevailed in reference to charges already made by the attending surgeons and consultants. Although such widely circulated statements are now proven to be without any foundation in fact, they have served as the bases for many learned articles upon the value of professional services, and in the majority of instances have been used as texts for the exorbitance of professional charges in general. It is now, we believe, generally understood that no formal bill will be presented. This, we believe, is a wise conclusion on the part of the staff in attendance, and removes from its members all the responsibilities of definitely fixing the value of medical services, and gives them an opportunity for placing the same above the mere level of pecuniary consideration. The case is a leading one in many particulars, and can be safely left to the chances of a suitable honorarium for each. The position of President Garfield, the circumstances attending the shooting, and the conditions of his after-treatment, naturally made him the Nation's patient; and there is no question, except in the minds of a very few, as to how and by whom the honorarium should be tendered. Evidently Congress is the proper medium through which the bestowal of any rewards should be made. There is no doubt that the desire of the people of the United States is to liberally compensate the gentlemen who have been in attendance, and that a suitable appropriation will be made in their behalf. In the case of an ordinary individual with ample means, the charges which could be legitimately made would be necessarily very high. The Nation demanded from the attendants upon the distinguished patient a sacrifice of all private business, and a readiness to respond to every call that might be made upon their time, to the exclusion of every other business consideration. That each and every member of the staff fulfilled such part of their duties no one can question. Whatever may be said concerning the degree of skill displayed in the treatment has nothing to do now with the estimation of the amount to be tendered to the staff. It is sufficient to understand that the parties employing the attendants were satisfied with the result of treatment, and were persuaded that nothing more could be done for the patient. But we cannot imagine that any objections can be urged on such grounds against the payment of a suitable sum for the services rendered.

In other countries, where similar services have been rendered, not only have large sums been voted in compensation therefor, but the governments have recognized them in an equally substantial manner by the conferring of titles and the bestowal of special privileges. Such examples cannot be followed in this country, save to a very limited extent. There is no doubt that the Government will do its utmost in the direction of showing its appreciation of the skill and devotion exhibited in the surgical care of our lamented President. The least that can be expected in this way is a formal vote of thanks by Congress to the staff, with the usual privileges attending such a recognition of distinguished services. This is possibly all that can be done in that line for the citizen surgeons. With the army officers who were in attendance the opportunities for expressing Governmental appreciation will not be so limited. The advancement in rank of both officers would be a becoming and graceful acknowledgment of work well done, and would be a direct and acceptable way of complimenting the profession of the country. These gentlemen were detailed by the Secretary of War for service at the bedside of the President, and, having faithfully performed their duty, are deserving of reward. It would not be without precedent to establish special grades for distinguished services, and this seems eminently fitting, in view of the danger of otherwise disarranging the legitimate lines of promotion. The time for the retirement of the Surgeon-General will soon arrive. If he be retired as major-general, Congress will have an opportunity of expressing, in an acceptable and becoming manner, its appreciation of faithful service. With the same disposition to do honor to Surgeon Woodward, an extra colonelcy might be created and he be promoted to that grade. These

are perhaps the only means which Congress can make use of, aside of the appropriations to be made, to reward each and every member of the staff according to his merit.

CONSULTATIONS WITH HOMŒOPATHS.

THE British medical man is not easily disturbed in the solid convictions that have been handed down to him, and he is particularly ready to resent any attempts to displace the established opinion of himself and his associates. The extreme ill-grace with which the most liberal overtures from the homœopaths in England have been met well illustrate this.

But during the past year there have been a number of occurrences which show that English medical men are being somewhat more disturbed than usual in their opinions; regarding this latter subject, they seem, indeed, to be actually changing them.

Dr. Quain, in his connection with Dr. Kidd, found support not only among the oldest and most eminent of London medical men, but he was defended by leading and representative journals. And now, despite the magnificent platitudes with which the *Lancet* lachrymosely discoursed upon the event, the profession in general has indorsed his conduct, while the Queen, it is said, will confer upon him the honor of knighthood.

The spontaneous and unconcerted utterances of Mr. Hutchinson and Dr. Bristowe, before the British Medical Association, furnish another evidence of a change of opinion upon this much-mooted subject of homœopathy. These gentlemen both expressed it as their deliberate opinion that the present antagonism toward homœopathic practitioners was unwise, and was also often ungenerous and unjust. While announcing this opinion, Dr. Bristowe showed with unapproachable clearness that, as a scientific system of therapeutics, homœopathy can have no standing.

But now comes an additional blow to the conservatives, and a still more remarkable evidence of a change of heart in the British practitioner. The Lancashire and Chesire branch of the British Medical Association recently refused to affirm the (in England) unwritten law of the profession that the practitioners of scientific medicine shall not meet homœopaths in consultation. The question is at once asked by the *Lancet*, "whether the members of this (the British Medical) Association are wholly given over to a libertine disregard of honor and consistency?" Whether the journal in question considers Mr. Jonathan Hutchinson and Dr. Bristowe as libertinous and dishonorable or not, we cannot say; but there must be something wrong in the logic which condemns these men, as well as a whole medical society, in so a sweeping manner.

It can be proved by abstract reasoning, no doubt, that a scientific practitioner and an old-fashioned homœopath have nothing in common. But it might be asked, if this is so, what is the necessity of forbidding by law the association of men who cannot associate. There is hardly need of regulations to enforce the impossible.

The broader principle seems to be, that educated, intelligent, and honorable medical men should be allowed to associate and consult, if they wish, whatever their special therapeutical views. But there may be a few, like Dr. Quain, Dr. Bristowe, Mr. Hutchinson, and the members of the British Medical Association referred to, who do not think in this way.

---

THE DEBATE AT THE NEUROLOGICAL SOCIETY, ON REFLEX DISTURBANCES FROM GENITAL IRRITATION.

THE paper and debate on reflex disturbances from genital irritation, which took place at the Neurological Society and is reported in this issue, will be read with considerable interest, both on account of the subject discussed and the prominence of the gentlemen who took part.

The points at issue can be easily stated. The reader of the paper, Dr. L. C. Gray, took the ground that there is no demonstrative evidence that genital (more particularly preputial) irritation can alone cause paralysis by reflex influence. He even asserted further that reflex nervous disturbances of any kind were rarely caused in this manner. In the cases, especially those of Dr. Sayre, which have been reported as illustrating such conditions, there was, he thought, lack of evidence in proof of the point claimed.

A careful study of the many facts presented at the meeting will enable one to draw some quite positive conclusions regarding the question at issue.

First, clinical and experimental studies show that reflex paralysis from preputial irritation is *à priori* a very possible thing. In addition, there are a few histories, such as that of Dr. Burchard's, which seem to prove that it has actually occurred and been observed.

Again, the evidence that there may be reflex paralysis from irritation or injury of some part of the sexual sphere is demonstrative, so far as clinical facts can demonstrate anything. In support of this may be instanced the cases of injured testes with paraplegia (Hammond, Spitzka), irritations of the urethra and bladder, and of the neck and body of the womb (Seguin).

Finally, the fact that genital irritation can cause reflexly all kinds of nervous disturbances, psychical, sensory, trophic, and motor, may also be considered an established one.

But, though the above conclusions may safely be formulated, they should always be mentally associated with certain other facts. Reflex paralyses

and other disturbances may, it is true, occur under the above conditions; but there are thousands of persons who have genital irritations and yet have no reflex symptoms therefrom whatever.

On the other hand, there are many cases—perhaps a majority—in which nervous troubles and genital irritations are combined; yet the latter stand in no causal relation to the former, and operations produce little or no effect. This side of the matter was but slightly brought out in the discussion, and only hinted at by Dr. Gray and Dr. Beard. We shall never have the records of the many cases in which prepuces were removed and meatuses slit with no benefit to the patient.

Now, from these last two series of facts there can be but one logical deduction: it is that genital irritation in most cases is only one factor in producing reflex disturbances. As regards reflex paralysis, such irritation is very rarely the sole or chief factor. It is a more efficient and frequent element in the production of functional nervous disturbances other than paralysis.

We may formulate this conclusion by saying that genital irritation is very frequently a causal factor in producing reflex nervous disturbances. It is not rarely an important causal factor, but it is very rare indeed that it is the sole cause.

The lessons from this debate are, not to accept too readily the view that paralysis or other nervous troubles in a given case are functional and due to an irritable prepuce, a small meatus, etc. At the same time the practical measures to be taken are not to be very much modified by theoretical considerations. The genital irritation should, as a rule, be removed, even if it is but a slight element in the production of symptoms, and even, in some instances, where paralysis is due to structural changes in the nerve-centres. One has only to remember, in making his prognosis, that improvement or relief may quite possibly not occur, or, at least, not be permanent. Furthermore, it is not so certainly established that circumcision and urethrotomy may not do harm. We had the curious fact brought out that circumcision may produce a contracted meatus, and this latter is a genital irritation for Dr. Otis, just as the tight prepuce is for Dr. Sayre.

---

Women's Hospitals in China.—The Women's Hospital was opened at Tienstin on October 8th, in the presence of Li Hung Chang and other Chinese officials of high rank. Mr. Angell, the United States Minister to Pekin, who is about to return by way of Europe, delivered an address. Miss Howard, M.D., the American missionary lady who was instrumental in the care of Lady Li, wife of the Viceroy, when her life was despaired of by all of her Chinese medical attendants last year, is in charge. The hospital just established in Tienstin, and another in Pekin, are solely due to the influence of Miss Howard. Foreign medicine in China is now in consequence in great favor.

# Reports of Societies.

## NEW YORK NEUROLOGICAL SOCIETY.

*Stated Meeting, November* 1, 1881.

Dr. T. A. McBride, President, in the Chair.

The paper of the evening was read by Dr. L. C. Gray, the title being,

### THE QUESTION OF REFLEX DISTURBANCES FROM GENITAL IRRITATION.

The speaker reviewed the history of the subject, and took the ground that the old theory that there might be reflex paralysis from diseases of the genito-urinary tract was not well founded. This view had after various discussions been quite generally accepted in Europe, until recently Brown-Séquard revived and expounded it again.

The subject deserved especial attention now, however, because Dr. L. A. Sayre had a few years ago announced the belief that paraplegias might be caused by preputial irritation. Dr. F. N. Otis had also claimed that many reflex symptoms of various kinds might be due to strictures, contracted meatus, etc. The speaker, therefore, proposed to examine the question: What evidence is there that genito-urinary irritation may cause reflex paralysis?

The cases reported by Dr. Sayre in support of his view were then read and analyzed seriatim. The speaker argued that in some cases the previous or subsequent histories were imperfect. In one patient the disease appeared to be really spinal hemorrhage, in another, an anterior poliomyelitis. A few cases, it was admitted, seemed to prove the reporter's view, but the details were incomplete, and they could not be cited in evidence. In all, the speaker said, Dr. Sayre had reported eighteen cases in proof of his position; yet not one of them, when critically examined, was sufficient.

In two cases the evidence was quite strong, so far as it went, but was incomplete.

In three cases there seemed to be impaired motion from the irritated genitals.

In one case there had been probably an intra-uterine spinal meningeal hemorrhage; in another, myelitis of the anterior horns.

In eleven cases the histories were too indefinite.

The speaker had received assurances from Drs. Weir Mitchell, Da Costa, Weber, Spitzka, Kinnicut, McBride, Hammond, Jewell, and others, that they had never met with any case of paralysis due reflexly to genital irritation. The speaker's personal experience agreed with that given by the above-named gentlemen.

In view of the foreging data, the conviction seemed irresistible that reflex paralysis could not occur from genital irritation, or, at least, occurred very seldom.

There is, however, good reason to believe that operative procedures often cause relief, especially in the later stages. There are cases in which the operation for phimosis is beneficial to the patient, although we know that the preputial irritation is not the cause of the disease. Thus, the speaker related a case of Dr. C. F. Taylor's, in which circumcision markedly relieved a post-diphtheritic paralysis.

Dr. Gray had had cases, in his own experience, which illustrated this: in one, the operation for phimosis relieved the paralysis temporarily, but the

symptoms returned, the child died, and autopsy revealed a tuberculous meningitis.

In a second case, the diagnosis of myelitis of the anterior cornua was made. There was a long and tight prepuce. After several months of ineffectual treatment, circumcision was performed. Great improvement resulted, which was maintained.

The third case was one of rhythmical tremor of the extremities (not of head or neck), which was increased by excitement and voluntary movement. There was diplopia. The patient, a man aged twenty-three, had worked in a brass-factory for several years and had inhaled the fine metallic dust. Diagnosis: tremor of disseminated sclerosis type, due to inhalation of brass. After treatment he greatly improved. He had phimosis, for which he was circumcised. For two months subsequently he had no return of tremor.

It must be remembered that when a genital irritation is removed by operation, we have several factors at work. An irritant is removed from an exquisitely sensitive organ, and the genitals obtain rest. The profound impression made upon the nervous system by chloroform or ether narcosis must be considered. There are many examples of the powerful results this may produce. The effect of the cutting operation in itself upon the nervous system may also be great.

The more excitable and impressionable the nervous system, the more active will these three factors be, particularly the latter two.

The cases cited by Dr. F. N. Otis show that removal of genital irritation will remove a host of nervous symptoms; but there are no data on which any man can judicially formulate an opinion that these symptoms might not be due to organic lesions.

The speaker was not prepared to deny that reflex paralysis might not occur from some causes. It is known that they can be produced in a limited way experimentally, by squeezing the kidneys of a rabbit, for example, or by cutaneous impressions, such as putting a rubber ring about the neck of a frog. Our knowledge of the inhibitory actions of the nervous system would also lead us to think reflex paralysis possible. But there is no proof which demonstrates that such a condition can result from genital irritation

The practical deductions are very important. We should never assume that nervous symptoms are due to genital irritation—we should search for organic disease. But genital irritation should always be removed. There is a great prevalence among Jews of a contracted meatus, due, no doubt, to circumcision. We should be careful not to deprive the glans of its covering unless it is necessary. Dr. Jacobi says that by simply breaking the adhesions of the prepuce he has succeeded in dilating the orifice.

While it is probable that slight nervous disorders can be produced by genital irritation, yet the proofs of even this are not complete.

In the discussion, Dr. L. A. Sayre said that the speaker had given him much information in regard to what might be the early or late history of the class of cases he had reported. Referring to Dr. Gray's statement, that the literature of the subject had received a number of contributions before the speaker published his cases, he said when he began the study of the matter he had considered himself first in the field. In standard text-books, also, he had been quoted as the first to draw the attention to the subject of paralysis from genital irritation.

The fact that some of his cases were paralyzed, and that, after operation, they recovered and remained cured, was one that could be demonstrated. Dr. Gray had intimated that in one case an apparent paralysis existed only because of the exquisite tenderness of the parts, which friction of the clothes increased. But if so, why could not the child move, as he could not, when perfectly naked? After circumcision, without any constitutional treatment, the patient recovered complete power.

It was hard to see how, in cases of paraplegia, where immediate and permanent recovery followed operation, there could have been any organic change in the cord. In such cases, where, as the reader of the paper had done, a diagnosis of organic change is made, he should be much inclined to doubt the diagnosis. He might not have been sufficiently careful in giving the minute details of his cases, but that they had paralysis and were relieved by operation he was positive.

The number of the speaker's cases confirmatory of his view had now increased to over one hundred.

The fact that the operation had now often been performed unwisely did not weaken the view that it was a necessary and useful one in its place.

The speaker recalled a case of paralysis from a blow on the outside of the leg. This showed that injury to the peripheral surface of the nervous system might cause paralysis.

To show also that paralysis might follow in other parts than the legs, the speaker read the account of a case sent him by Dr. Knapp.

The following is the history of the case:

Louis H——, German, aged thirty-four years; married four months; very stout and active, "but very nervous, getting tired very easy." Eight years ago began to have trouble with his eyes, finding that he could read only a little while at a time, getting then so nervous that he would throw his book away, and could not again read for some hours. Can now read only a very few minutes at a time, and very large print; has consulted various surgeons in Europe and here, without benefit; sent to me Feb. 20, 1875, to be operated upon for phimosis.

Has never seen the glans penis. Prepuce very tightly contracted, elongated, and twisted to the right side.

February 22d.—Cut off the end of the prepuce and divided mucous membrane—which was very tough and thick, almost fibro-cartilaginous—with bistoury down to the corona; stitched mucous membrane to tegumentary prepuce, and dressed with oiled rag.

February 23d.—Very comfortable; no inflammation.

At the end of one month he was perfectly well and could read, and did read in my office a whole page of the *American Journal of Medical Sciences*, even down to the fine print, "Entered according to Act of Congress, etc.," at the bottom of the page, without the aid of glasses or being at all fatigued.

In regard to the improvement in the eyes, Dr. Knapp wrote Dr. Sayre under date of November 14, 1881, as follows:

"My Dear Doctor: I recollect the patient well. His sight after the operation had materially improved, both as to acuteness and capacity for prolonged use. He has consulted me several times since. He has still incomplete atrophy of the optic nerves, and moderate amblyopia; yet I consider it a great result that the atrophy has not progressed, and the patient always expressed his satisfaction and gratitude to you.

"With kindest regards, yours very truly,

"H. Knapp."

November 14, 1881.

Dr. F. N. Otis said that he had come there hoping to learn something new, but he had been disappointed so far, except as regards what Dr. Sayre had said about the permanence of his results. The speaker had not seen cases of paralyses of the kind described by Dr. Sayre, but he believed in their existence on account of the many analogous cases met with in his own practice. He believed that there was something more than coincidence in the histories of all kinds of nervous disturbances becoming at once relieved after removal of a genital irritation.

The speaker related the case of a prominent medical gentleman of this city, who suffered from melancholia to such an extent as to interfere with his business and all his habits. He consulted Dr. Otis for a urinary irritation. A contracted meatus was found. In making an examination, the meatus was considerably dilated, it being done without expectation of its affecting his general condition at all. Nothing more was done. The patient came back in three or four weeks, saying that the intense relief to his melancholia had been so indelibly associated with the distention of the meatus, that he wished the operation repeated. This was done, and relief again obtained. The operation was repeated at intervals of three or four months for several years, the patient objecting to urethrotomy. The meatus was finally permanently dilated, however, after which he had no mental trouble whatever. In this case the speaker recognized a distinct reflex influence of the genital irritation upon the brain; he did not think it was a coincidence or a case of organic disease. A similar case, relieved by removal of prepuce, was related. Many cases of seminal weakness, and of various other nervous disturbances, which disappeared after removal of the prepuce, could be recalled.

A gentleman of this city, fifty-eight years of age, had called on him once, saying that his wife had died about a year before. He had recently attempted to have connection, but had ignominiously failed. Yet he did not think himself old enough to have lost all sexual power. The speaker found an irritable prepuce, with much sebaceous matter upon the glans. Circumcision was performed and sexual power restored.

The speaker had met with so many cases of this kind, that he had come to look upon the prepuce as of no use, and considered persons better without it.

With regard to the Jews, who, it has been said, had, in the majority of cases contracted meatuses, he thought this true. But, on the other hand, a great many people have contracted meatuses anyway, just as every one has some slight physical defect of some kind or other.

It did not make much practical difference in treatment, because the persons were better with the meatus enlarged, whatever the theory.

The speaker announced his very positive conviction that reflex paralysis from genital irritation was possible.

He related the case of a boy, who, two years ago, was brought to him complaining of lameness and showing some of the symptoms of hip-joint disease. The patient had phimosis, and circumcision was performed. This gave some relief. A short time ago the boy was brought back with many of the former symptoms. The thigh and leg on the affected side were slightly atrophied. The meatus was found to be contracted to 12 when it should be 22. Dr. Otis dilated to 22, and had recently received a note saying that the lameness had disappeared entirely.

Dr. Sturgis thought that there could be no doubt regarding the existence of reflex irritations. With regard to the question of reflex paralysis, he would suggest that, so far as the evidence of Dr. Sayre's cases went, the verdict of not proven might be given. Still there was no reason to suppose why genital irritations in men should not produce paralyses similar to the hysterical paralyses that occur from like causes in women. He recalled a case of paraplegia in a woman suffering from gummous ulceration of the neck of the womb. The paralysis appeared to be due to organic lesion. But a sudden fright caused the woman to get up out of bed.

The speaker thought that the claim of Dr. Gray was too sweeping. He suggested that the matter might be put in another way, and that it might be said that the claims of the reader of the paper that there was structural disease in these cases was not demonstrated.

Dr. E. C. Seguin said that his experience was that reflex troubles might occur from preputial and other genital irritations. He agreed with Dr. Otis in reference to most of that gentleman's statements. He had never seen a case of reflex paralysis from irritation of the male sexual organs. But every day he saw cases of paralysis due to structural diseases of the cord, which had been operated on as cases of genital irritation. He did not deny that there were any cases of reflex paralysis from genital irritation, but he was waiting to see a case of that kind. He believed in relieving genital irritation, but he would not operate with hope of relief in cases of contracted legs or paralysis with wasting in which there were undoubted evidences of disease of the cord.

With reference to the Jews, he had found that they did have contracted meatuses. He had had a great many Jewish patients, and almost every male examined had this defect. He thought, also, that the Jews presented, with a remarkable degree of frequency, reflex irritation of the sexual apparatus.

The speaker had a number of cases sent him by Dr. McGuire, of Washington, D. C., but there was not time to read them. We publish them in this connection. Dr. McGuire is physician to the Department for Diseases of Children, Central Dispensary. In the past year he writes that he has examined the genitals of seventy-five boys complaining of nervous symptoms. In nearly every case he had found either elongated prepuce or adhesions, or both. Amelioration, and more frequently success, followed removal of the abnormal condition, almost always without the assistance of drugs.

Case I.—J. M——, aged eighteen months, had been troubled with incontinence of urine for several months. Prepuce much elongated. Performed circumcision January 15, 1876. No medicine was given. Perfect relief obtained. No return of trouble to this date.

Case II.—J. W——, aged eight. This boy had continual incontinence of urine for several years. Drawers were always wet. Prepuce much elongated and adherent. Performed circumcision April 16, 1880.

May 13, 1880, the dribbling during the day has almost ceased. He has passed water in bed four times at night since the operation—the first time three days after the operation. Small doses of strychnia were given. There was marked improvement, but not perfect success. Medication was continued At present he is well.

Case III.—G. T——, aged ten. April 15, 1880, complained of constant pain in popliteal space of left

leg, great weakness of the legs, headache, palpitation on the least exertion. Broke down adhesions, which extended to orifice of urethra; gave no medicine.

June 22, 1880, perfect relief; no return of symptoms.

CASE IV.—January 15, 1880, John D——, aged nineteen months, cannot walk, stands with difficulty; head is thrown well back; is peevish, restless, and bow-legged; whines continually. Ordered malt, cod-liver oil, and hypophosphites. May 6th, the child is stronger, but the above symptoms still persist. Examined penis. Adhesions broken down and smegma removed. Medicine continued. May 20th, marked improvement; adhesions had reunited. Again broke them down. August 16th, child walks readily.

CASE V.—John B——, aged two, has great muscular debility of the lower extremities; locomotion difficult. Prepuce elongated. Circumcised June 21, 1880. 28th, much stronger, walks better. August 16th, improvement continues. There is slight inclination to talipes valgus. This case has required constant care to the present time. His condition is very favorable.

CASE VI.—July 29, 1880, W. Williams, aged three, cannot walk readily. Has incontinence of urine. Broke down adhesions and removed a large amount of smegma. October 18th, no return of incontinence. Walks much better.

CASE VII.—Charles N——, aged six. This child was very backward in walking; is now weak in lower extremities; has incontinence of urine, and inguinal hernia. August 5, 1880, broke down adhesions, and removed a quantity of smegma. August 19th, marked improvement. September 6th, much stronger. No return of incontinence.

CASE VIII.—C. R——, September 23d, aged two and one-half. Is unable to stand; very little power in legs; muscles of thigh loose and flabby. Circumcised and broke down adhesions. Ordered malt and hypophosphites. October 31, 1881—to-day the child runs around readily.

CASE IX.—Jos. W——, aged two. August 16, 1880, walks with great difficulty, drags his legs, and is easily pushed down. Adhesions were broken down. August 23d, walks without dragging his legs. September 27th, circumscised. October 4th, marked improvement. The progress in this case was not so decided as in others. Gaiffe's battery was applied This seemed to be beneficial.

CASE X.—Pierce W——, aged two. Stumbles on coming in contact with the least elevation, walks very awkwardly. Slight talipes varus. Circumcised and broke down adhesions. Marked improvement.

CASE XI.—Wm. F——, aged three. Is unable to stand; has laryngismus stridulus. Muscles of thighs and legs very poorly developed. The laryngismus was treated for one week, without any improvement. Then he was circumcised, and the treatment continued. One week later this was better, and he could stand by a chair. Improvement was continuous and rapid.

CASE XII.—Willie B——, aged one. Is very weak throughout the whole left side. This side is not so well developed as the right. He drags the left foot when he crawls, and has had frequent convulsions. Circumcised and broke down adhesions. Three weeks later the child had much better use of his extremities. The improvement continued. Electricity was used.

CASE XIII.—Edward T——, aged eleven. Incontinence of urine. Broke down adhesions. No improvement.

CASE XIV.—William E——, aged four. This child had a severe case of talipes equino-varus. The tendo Achillis was cut and the foot brought into position. About four months afterward, I noticed the prepuce much elongated. Circumcised and broke down adhesions. Brace was applied and electricity used. The improvement was rapid and excellent.

CASE XV.—Richard G——, aged four. Incontinence of urine. Circumcised and broke down adhesions. Perfect relief.

CASE XVI.—William B——, aged thirteen. This boy had convulsive seizures almost continually—sometimes forty or fifty in the twenty-four hours; would awake and scream out during the night; easily excited, and would at times be almost uncontrollable. Prepuce elongated and adherent. Broke down adhesions, December 15, 1880. Ordered no medicine. I saw him again January 11, 1881. He had not taken any medicine since I broke down the adhesions one month ago. The attacks during the day recurred very rarely. The night attacks were much less severe. Circumcised him October 23, 1881. The improvement has been decided and continuous. For a while after the circumcision there was immunity from the convulsive seizures for a week or more at a time. Then they would return occasionally at night. To control this, bromide of potash was given. Now he goes to school regularly. His teacher gives excellent reports of his behavior and progress in his studies.

CASE XVII.—Joseph L——, aged six weeks. This was one of the most interesting and pronounced cases that has ever come under my observation. He had never had a good night's rest since his birth, and had to be drugged to secure the least rest. He cried almost incessantly night and day. The legs were in constant motion, sometimes striking the abdomen. The penis was in a state of priapism. As soon as it was touched, the convulsive movements were augmented in severity and rapidity. In each inguinal region small tumors appeared when the child cried. I circumcised him March 28, 1881. As there had been such severe muscular action, I ordered half-grain doses of chloral every hour until quieted. During the ensuing four days he took eight grains of chloral; then medicine was discontinued. All the nervous symptoms had disappeared. The child slept readily. Three months after the operation, the mother informed me that from the second day thereafter she had not had a particle of trouble with her boy.

CASE XVIII.—B. P——, aged ten weeks. Had not had a good night's rest since his birth; cried and fretted almost continually; was in constant jactitation. The urine would accumulate under the prepuce and dribble out through a very small orifice. The head was thrown back on the spinal column. The mother said that she used to pass a handkerchief around the head and fasten the ends of the handkerchief to the belly band to keep it erect. Performed circumcision. Did not order any medicine. Every symptom of irritation disappeared. Three months later there had not been the least evidence of return.

CASE XIX.—A. F——, aged thirteen, had shown great muscular debility in the lower extremities from birth, especially in the left leg. This leg would give way under him; he would fall in the street and around the house. He complained of dizziness and pain in the lumbar region; also had

nocturnal incontinence of urine. Prepuce firmly adherent, almost to the orifice of urethra. I broke these down January 19, 1880. No medication was employed. There was no return of a single symptom, except upon one occasion there was incontinence of urine. He has continued to grow stronger, and is to-day (October 31, 1881) brighter than ever before.

Dr. G. M. Beard said that he had been engaged in studying the subject from a neurological standpoint for a considerable time. He had presented some of his conclusions in a general way at the meeting of the American Medical Association two years before.

He believed, in the first place, that the great majority of persons who have either a contracted meatus, or redundant prepuce, or phimosis, are just as well as anybody else. From this it might be presumed that genital irritation was not the sole cause, at least of reflex troubles.

As regards his own experience, he had found that the result of operations for the removal of genital irritation had been generally very unsatisfactory. The cases, however, in which he had had the operation done were generally those of that condition—call it what one pleases—of neurasthenia, cerebral hyperæmia, or anæmia, etc. In some cases there had been slight improvement; in one case this was very marked.

In judging of the results, the action of the mind on the body must be taken into account.

Dr. Agnew, of Philadelphia, had told the speaker that he operated once for preputial irritation, and it helped the patient. In fifteen or sixteen other cases it did no good at all. Dr. Beard thought that the Jews were quite subject to nervous troubles, despite the absence of a prepuce. He was of the opinion that circumcision might actually do harm. He recalled one case in which impotence followed the operation.

Dr. E. C. Spitzka had never seen a case of reflex paralysis from genital irritation. But he had some strong reasons for thinking that it might occur. There was now at the Central Park Menagerie an eland with posterior paralysis, which followed the tying of an elastic ligature around the scrotum for the purpose of altering the animal. The speaker also referred to a case of posterior paralysis in a horse, in which the only lesion, except a few cysts in the ovaries, was an extensive, though but slightly progressed, nephritis. It is generally recognized that posterior paralysis in horses points to renal disease. In almost every form of renal disease paraplegia may occur.

Dr. William A. Hammond said that while it was true he had never seen a case of paralysis due to genito-urinary irritation, yet he had seen paraplegia following injury; for example, in a dragoon whose testicles were smashed. He had seen several cases of paraplegia following strong urethral injections, and had seen it apparently result from cystitis.

The speaker was prepared to admit, therefore, that preputial irritation can give rise to a paraplegia.

He did not see how Dr. Gray could refuse to admit the various paralytic troubles and hysterical symptoms that occur in females from genital irritation. He must be familiar also with the fact that catheterization of the male sometimes produced syncope, which was the evidence of a partial heart-failure or paralysis. Dr. Gray might, perhaps, make out his case if his position were that preputial irritation had not been shown to be the cause of reflex paralysis. As regards genital irritation in other parts, however, the claim of the reader could hardly be sustained.

Dr. Burchard said that he thought it but due to his friend and former preceptor, Dr. Sayre, to relate a case in which there was unmistakable paraplegia dependent on preputial irritation due to phimosis. It was entirely cured by an operation, and the patient had subsequently been under his observation, so that he knew that the cure was complete.

The patient was a young man who had paraplegia and strabismus. He had for several years been under the care of eminent surgeons and neurologists in this country and France. These gentlemen had considered it a case of paraplegia due to organic change in the spinal cord. The speaker saw him at Saratoga, inconnection with Drs. Hamilton, McBride, and Lente. The penis was found to be excessively sensitive, so that the merest touch caused intense reflex symptoms. The prepuce was very long, the penis quite diminutive. An operation was performed, and within a week after the patient had lost all his paraplegic symptoms. His strabismus had also disappeared, his gait was as perfect as that of any one, and he was absolutely cured.

Regarding the early history of the patient, the mother had said that when a boy he suffered a great deal from irritation of the penis. At the age of ten or eleven these symptoms disappeared. After this the paraplegia slowly developed. He was sixteen years old at the time of the operation.

In the same summer the speaker saw a patient who had been under Dr. Loomis' care for epilepsy. Dr. McBride had seen him in an epileptic fit. This patient had phimosis. The prepuce was removed, and since then no fits had occurred.

Dr. Birdsall thought that one point had been lost sight of in the discussion. Dr. Gray had referred to the different factors at work in the cure of this class of cases. One of them was the removal of the irritation, but another was the effect upon the nervous system of the operation itself. The experiments in nerve-stretching for such diseases as locomotor ataxia, neuralgias, etc., showed that injuries to the nerves had a powerful effect upon the system in general.

The speaker had recently had his attention called to the cases of Hebrew children where circumcision had been performed, and where excitation of the genital organs caused just as much trouble as if circumcision had not been performed. In another case circumcision had been performed without benefit.

Dr. Spitzka recalled two cases of paraplegia due to organic disease. Dr. Sayre had seen them and pronounced them unfit for operation. In both cases an operation was performed; in one of them some harm resulted.

Dr. Seguin said that he had never seen cases in which the operation had done harm. He had, on the other hand, seen a number of cases in which temporary improvement took place.

The speaker added that he had seen paralysis result from irritation of the sexual sphere, from irritation of the deep urethra, and from disease of the womb. He was not sure that he had seen paraplegia from ovarian disease. He had seen two cases in which treatment of uterine disease brought about cure. One was a case of laceration of the cervix with partial paraplegia. The other was a lady from Bermuda, who had subinvolution with marked paraplegia. She recovered very rapidly under proper treatment for subinvolution.

Dr. Gray, in closing the discussion, said that he

had been misapprehended in several points. He had distinctly given Dr. Sayre the credit of having made the subject under discussion known to the profession. Dr. Gray then reviewed briefly the position he took and the argument he had made. He said in conclusion that, up to the time of the present meeting, there had not been in his opinion demonstrative proof that reflex paralysis or irritations could be produced by genital irritation alone. He was not yet convinced by what had been said that his position was an incorrect one. Yet some of the facts recently given needed careful analysis and study.

[Dr. Sayre had a number of other cases which he intended to have read, but, through a mistake, the records were left at home. We insert some of them here.

CASE I.—*Partial Paralysis and Inco-ordination from Phimosis.*

June 15, 1875.—Henry Behrens, aged thirty-one months, 207 Graham Avenue, Williamsburg. Began walking when about a year old. Until twenty months of age he ran around freely and seemed to notice everything, being able to understand much that was said to him, and to call papa and mamma, and to say some other simple words. Up to that time had slept tolerably well, ate well and properly, as any other child. At twenty months of age was noticed to become nervous, moving his hands and feet in a peculiar way, and making a strange noise. In a few minutes would pass water, and then seemed to be free from all these symptoms. Would sit still all day in a chair, if left to himself, without noticing anything or attempting to speak. If he attempted to walk, his gait was unsteady, and he would fall forward to the floor. He never seemed satisfied with what he had to eat, always stuffing his food into his mouth as if he were starved, and acted and looked idiotic.

*Present condition.*—Very unsteady gait, moving about as if he were intoxicated, and falling down after every few steps. Elongated prepuce, with extremely small orifice.

*Treatment.*—Circumcision; found mucous membrane adherent, which was torn back. Smegma removed from behind the glans, and dressed wound with styptic cotton.

July 1, 1875.—Returned in perfect health, and could walk with steady gait. Was bright and cheerful, and, his mother said, was anxious to play with other children, and talked quite freely.

CASE II.—August 20, 1875. Frank R. Gordon, six and one-half years of age; Nunda, Livingston Co., N. Y. Partial paralysis; cannot extend his legs without assistance. His father states that he was constantly stumbling over the smallest objects. Had constant erections and was always handling his privates. Made examination and found prepuce firmly adherent to glans penis. Introduced director and slit prepuce; the adherent portion torn back, found where glans was uncovered a thick roll of sebaceous material behind the corona, which was removed.

Have since heard, by letter of October 10, 1875, that the child was very greatly improved, could stand and walk without stumbling, and extend and flex his limbs without any effort.

DR. SAYRE:

*Dear Sir*—The cases of epilepsy that I reported to you, arising from preputial adhesions, are still free from the disease, not having had a single paroxysm since breaking up the adhesions.

I have seen another case of epilepsy in a boy four years of age, with adhesions of the prepuce to the corona. I separated the adhesions (gave no medicine in the case) six weeks ago, since which time he has not had a single convulsion.

Yours respectfully,

DR. W. R. MCMAHAN.

HUNTINGBURG, DUBOIS CO., IND., April 11, 1876.

CASE III.—April 29, 1875. Charles Edward Burdick, eighteen months of age; 218 West Twenty-eighth Street. Young mother. First child, robust and healthy from birth. Began walking at nine months, but lately has been unable to walk, or even stand, his legs giving way under him. Was always a poor sleeper; never had convulsions.

The mother has noticed the condition of the child's penis for some time, but supposed it was natural until Dr. E. D. Morgan was consulted in regard to a sudden illness of the child, and discovered the abnormally excited penis, and advised her to see Dr. Sayre.

*Present condition.*—Penis unusually developed; prepuce adherent just outside of the meatus urinarius, the urethral orifice being red, patulous, and granular.

The scrotum and inner side of the thigh excoriated, as the mother states, from scratching. Child falls and stumbles in walking around the office.

*Treatment.*—Prepuce torn back with the thumb and finger, exposing a very large glans penis for a boy of his age, and behind the corona an unusual amount of hard, thickened smegma, closely adherent, requiring such force in its removal as to leave a bleeding surface around the glans.

Frænum also torn, followed by hemorrhage, which was checked by styptic cotton. The same evening the parts were œdematous from constriction. Prepuce was then nicked on the anterior surface, and needle-pricks through the integument, to let the serum ooze; otherwise doing well. Dressed with plumbii acet. and water.

May 12, 1875.—Entirely healed; child greatly improved.

June 1, 1875.—Child returned; could cover and uncover glans without constriction. His mother states that he can run and play without falling down, which he formerly could not do.

CASE IV.—March 25, 1875. John Lovatt, aged three and one-half years. Began to walk at nine months; walked very well for three months; his mother then noticed that he was somewhat lame and would fall at every few steps; was very restless at night—always wanted to be in a sitting position.

On examination, found partial paralysis and atrophy of the left leg; would throw foot out at each step. Penis very small; glans had never been uncovered; penis constantly erected.

Phimosis removed by circumcision; mucous membrane torn back.

September 30, 1875.—The child returned very much improved; walks much better, and his mother states that he runs about the house, for the first time in two years, without falling down; also, that his appetite is better, and that he sleeps *lying down* without waking during the whole night, and has done so ever since the operation.]

THE HEALTH OFFICER OF THE PORT OF NEW YORK.—An investigation into the matter of this officer's income shows that it amounts to about $50,000 annually.

## AMERICAN ACADEMY OF MEDICINE.

To the Editor of The Medical Record.

Dear Sir: If the membership of the American Academy of Medicine is limited to those possessing the degree of A.B. or A.M., as stated by the secretary, Dr. Dunglison, in your issue of November 5th, is it not somewhat unjust to many of the profession who have taken the scientific instead of the classical course in our colleges, in order to avail themselves of the increased advantages offered in the study of chemistry, toxicology, and other branches more nearly allied to the present science of medicine than the pursuit of the study of the Latin and Greek beyond the elementary stages.

Should not the degree of B.S. (Bachelor of Science), M.S. (Master of Science), or Ph.D., be an equivalent to A.B. or A.M. as a qualification for membership in the American Academy of Medicine?—for they represent college attainments more necessary to success in the profession than either A.B. or A.M. Then, again, if a college confers the degree of A.M. upon a man who has not received it by the regular course of study, does this qualify him for membership in the Academy, if he has previously received the degree of B.S. or M.S. in regular course in a college, where the degrees of A.B. and B.S. represent a similar amount of work?

Very respectfully,

M.S.

To the Editor of the Medical Record.

Dear Sir: I have been much interested in the discussion concerning the American Academy of Medicine, in The Record of October 8th and November 5th. It seems to me that, if there is any reform for which the medical profession is ripe, it is one which shall radically change the present system of medical education; and that, if there is any place for a new association of medical men, it is for one which shall energetically agitate and advocate such a reform. Dr. Dunglison, in his communication of November 5th, states the aims and purposes of the American Academy of Medicine as follows:

*First.*—To bring those who are alumni of classical, scientific, and medical schools into closer relation with each other.

*Second.*—To encourage young men to pursue regular courses of study in classical and scientific institutions before entering upon the study of medicine.

*Third.*—To extend the bounds of medical science; to elevate the profession; to relieve human suffering; and to prevent disease.

The first of these articles of belief, if I may so denominate them, calls for little attention, for its aim seems to be entirely gregarious or social, and might figure quite as aptly among the articles of incorporation of an association of liberally educated men. The third is scarcely more specific or distinctive, for its aims are those for which all medical men should labor.

It is the second article which I desire especially to discuss, for its aim is one which, if properly understood and energetically and wisely carried out, would, in my estimation, be a sufficient reason for existence for any body of men having the honor of the profession and the welfare of humanity at heart.

Does this society, then, fully comprehend the importance of this aim, and is its action likely to elevate the standard of medical education? I think the question must be answered in the negative. For a mere social gathering of medical men, to whom favoring fortune has rendered a classical education possible, a yearly meeting may suffice; but much harder work lies before any association having the cause of medical education really at heart. Nor can I think that, by encouraging young men to pursue courses of study in classical and scientific institutions, preparatory to their medical studies, the cause of medical education can be materially advanced. First, because a very small percentage of those choosing the profession of medicine have the time or means requisite for those studies which are necessary for the procurement of a classical or scientific degree; secondly, and principally, because such a course would not be wise for the great majority of medical students. The very fact, adduced in the above-mentioned communication, that even a smaller percentage of medical men in England take classical or scientific degrees than here, sustains me in this point; for who, familiar with the subject, believes that it would be well to urge young men generally, who desire to enter the medical profession, to spend four years in gaining a literary degree—four years spent mainly in the study of the dead languages and the higher mathematics, and with only the most remote reference to the study of their choice.

I do not wish to be misunderstood, for none more than I can appreciate the advantages of a liberal education for medical men; but art is long and life is short, and at least half of the time spent in acquiring the degree of A.B. in any one of our colleges might be much more profitably spent in the pursuance of those studies which should be preliminary to medicine proper. And just here is the reason why, in England, where classical learning certainly does not lack appreciation, so few medical men take a classical degree. For, while they have not pursued the study of the ancient classics or pure science to the extent which would entitle them to a degree, yet they are *all* familiar, to some extent, with classical and scientific knowledge. There, every student of medicine must pass a preliminary examination equal, in many respects, and superior in some, to that required here for admission to our colleges; and while from the moment he enters upon his studies all points to the goal he desires to reach, still the course marked out is not cramped and narrowed as here, but broad and liberal, so that finally, when he graduates in medicine, he is not only a physician, but a man of truly liberal education. For the few who have time, or those who do not early decide upon their path in life, nothing here presents itself better than our college course; but would you consign to it him who, fortunately, early in life has chosen his career? It is claimed that the study of the classics and mathematics disciplines the mind, and trains to thought and analysis. To a certain extent this is true; but is the field of medical science and those subjects allied to it not large enough to teach exact thought? And may not the student of medicine peruse Hippocrates with more profit than Homer? What we need is a truly liberal *medical* education for medical men. Let it be required of every student of medicine that he have a good English education; that he know something of Latin and Greek, and of natural history;

and above all, he should not receive his degree until he knows enough of medicine to begin its practice, and be aware of the immense field which lies before him, and of his great duties and responsibilities. Much might be said upon this subject, and upon the necessity of a State board independent of the medical colleges; yet I fear to trespass further upon your space, and will only say in closing, that I hope some day to see a society formed of medical men who have the reform in medical education at heart, and who shall be able to accomplish it.

I remain yours faithfully,
S. S. JONES, A.B., M.D.

## CONSULTATIONS WITH HOMŒOPATHS.

### A REPLY TO "ETHICS."

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: It appears, from what "Ethics" writes in the RECORD, that he desires to take issue with me upon my criticism of Dr. Bristowe's remarks touching consultations with homœopaths; but wishes me to state, as preliminary to the discussion, my definition of the meaning of homœopathy and homœopathic practice, in contradistinction to the doctrines and practice of the regular profession. I had not known before that such a definition was a matter of individual opinion—that the distinctive characteristics of each had been so nearly obliterated as to render a proper definition a matter of doubt. I cannot yet believe that such is the case; therefore I must decline to comply with the wishes of your correspondent in this regard, and must suppose that, if he is competent to discuss the question at all, he understands perfectly the peculiar tenets, a belief in and the practice of which have ever separated the followers of Hahnemann from the regular medical profession; if he does not, I am afraid I cannot enlighten him. I hope this position of mine, however, will not prevent "Ethics" from stating his view of the question concerning which he joins issue with me; though I must certainly insist that he do so over his own signature, for it is unpleasant for me to communicate, either upon paper or orally, with one whose name at least I do not know.

J. B. STAIR, M.D.

SPRING GREEN, WIS., November 8, 1881.

PERCHLORIDE OF IRON.—Casarini advocates this remedy in certain skin affections (*Lo Spallanzani*, 1881), and concludes: 1st, that the perchloride of iron externally is the most efficacious remedy against purpura hemorrhagica and purpura simplex; 2d, that it is very useful in the cachectic chloro-anæmic condition, which often accompany certain affections of the skin, as rupia, ecthyma, impetigo; 3d, externally this remedy exercises a prompt and favorable influence over ulcers dependent upon scrofula and constitutional syphilis; 4th, employed as an ointment, it is an energetic and efficacious modifying agent in desquamating affections of the skin, as psoriasis; 5th, it may be used in the form of lotions with 2–3 parts of water, or as an ointment containing 1–2–3 grm. of the perchloride to 30 of lard.

Casarini has used the remedy in psoriasis in the proportion of 10 grm. to 30 of lard or glycerine, with satisfactory results, especially when glycerine was employed.—*Riv. Clin. di Bologna*, August.

## ARMY NEWS.

*Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 6, 1881, to November 12, 1881.*

KING, WILLIAM S., Colonel and Surgeon. The extension of leave of absence on account of sickness, granted him in S. O. 105, May 7, 1881, from A. G. O., still further extended six months on account of sickness. S. O. 251, A. G. O., November 7, 1881.

WRIGHT, J. P., Major and Surgeon. Granted leave of absence for twenty days on surgeon's certificate of disability. S. O. 229, Department of the Missouri, November 8, 1881.

MCCLELLAN, ELY, Major and Surgeon. Now awaiting orders at Louisville, Ky., to report in person to the Commanding General, Department of the East, for assignment to duty. S. O. 252, A. G. O., November 8, 1881.

HARTSUFF, ALBERT, Major and Surgeon. The leave of absence granted him in S. O. 214, October 20, 1881, Department of the Missouri, is extended nine months, with permission to go beyond sea. S. O. 251, A. G. O., November 7, 1881.

MEACHAM, F., Capt. and Asst. Surgeon. To accompany from Fort Trumbull, Conn., to the Military Division of the Pacific, Batteries C and M, First Artillery, ordered to start on 11th inst. Upon completion of this duty to rejoin proper station in Department of the East. S. O. 66, Military Division of the Atlantic, November 8, 1881.

FINLEY, J. A., Capt. and Asst. Surgeon. To accompany from Fort Adams, R. I., to the Military Division of the Pacific, Light Battery K and Batteries B and E, First Artillery, ordered to start on 14th inst. Upon completion of this duty to rejoin proper station in Department of the East. S. O. 66, C. S., Military Division of the Atlantic.

TURRILL, H. S., Capt. and Asst. Surgeon. To accompany Battery H, Third Artillery, from Madison Barracks to New York city, and on arrival report in person at these headquarters for further orders. S. O. 67, Military Division of the Atlantic, November 9, 1881.

CARTER, E. C., First Lieut. and Asst. Surgeon. To accompany from Fort Adams, R. I., to the Military Division of the Pacific, the headquarters, band, Battery F, and detachment Light Battery K, First Artillery, ordered to start on 10th inst. S. O. 66, Military Division of the Atlantic, November 8, 1881.

RAYMOND, H. J., First Lieut. and Asst. Surgeon. To accompany Batteries A and D, First Artillery, from Fort Columbus, N. Y. H., on 10th inst., for San Francisco. S. O. 66, C. S., Military Division of the Atlantic.

VACCINATING FOR SPLENIC FEVER.—The practical application of vaccinating against anthrax has been made very extensively in France. M. Bouley recently announced the inoculation of forty thousand sheep. M. Pasteur states that he has all that he can do to supply the demand for his anthrax vaccine. In the department of Haute-Marne, France, the authorities have decided to test protective inoculations on a large scale. It is interesting to know that cases of supposed anthrax have recently appeared in New Jersey. The State Board of Health have sent specimens of blood to be examined and tested at Dr. T. E. Satterthwaite's laboratory in this city.

THE PROGRESS OF HOMŒOPATHY.—We notice in one of our exchanges that the word Homœopathic has been dropped from the title of the society formerly known as the Homœopathic Society of Northern New York. A step in the right direction.

EXPERIENCES OF A COUNTRY PRACTITIONER.—A writer in the *American Specialist*, in an article on the country doctor, gives some interesting and suggestive experiences. After referring to a visit made at the end of a weary day, to see a wealthy(?) patient six miles away, who had bitten his tongue during a spree, and upon whom he was compelled to make a second visit, only to find his patient absent from home, and received for all his trouble a single fee of one dollar, thus refers to the situation: "I had suffered much inconvenience and had driven twenty-four miles for one dollar. This would not pay for the wear and tear of my carriage. Though an exaggerated, this is not an exceptional, case of the kind. A similar case occurred to me one cold, snowy morning, when I was awakened at half-past five by the word that Mr. So and So, who lived some four miles away, was very sick and wanted me at once. Dressing in a hurry, I drove in great haste, and when I arrived, half frozen, at my destination, I found an indolent ulcer some three or four months old and about the size of my thumb-nail. I had to swallow my indignation as best I could, and wash it down with a cold breakfast. I was aroused one night, at twelve o'clock, with the word that a woman whom I had been engaged to attend was in labor. She lived five miles away. They had neglected to send a wagon for me. My man was away, so I was compelled to open the stable and harness my horse myself. Shortly after I reached the house it commenced to rain. The father of the coming baby took the horse from the wagon and led him to a shed; when passing behind him my horse became frightened and kicked the man on the leg. The pain was so great that he fainted. I was obliged to leave my patient, and going out into the pouring rain, carry the man to the house, and minister to his needs. Just as I had succeeded in restoring him to consciousness, I was hastily called to the next room. I found the child's head engaged in the vulva, and finally, about five o'clock, the child was born, when I had to add the preliminary duties of monthly nurse to those of accoucheur. Then followed a five-mile drive home in the rain, a thorough wetting, and a subsequent cold. During the next week I paid five visits to my patients. These were very well-to-do people, and, after waiting six months, I received ten dollars for my labor, and was generally considered a very *dear doctor* for asking so much. The most liberal patient I ever had lived in Chester (nine miles from my home), whom I used to visit every week, until I became too busy to spare the time. She was wonderfully generous, and paid me two dollars for each visit; two dollars for eighteen miles."

ANNUAL REPORT OF THE SURGEON-GENERAL OF THE ARMY.—The annual report of Surgeon-General Barnes has just been submitted. The cost of medical and surgical supplies during the year was $183,-253 42. He asks for $250,000 for the coming year. Respecting the health of the army, the report shows that among the white troops the total number of cases of all kinds reported on the sick list during the year was 37,408, being at the rate of 1,768 per 1,000 of mean strength. Among the colored troops the total number of cases reported was 4,650, or 1,984 per mean strength. The total number of deaths from all causes among the white troops was 197, or 9 per 1,000 of mean strength, and the total number of deaths of colored soldiers reported from all causes was 48, or 20 per 1,000. Renewed attention is invited to the necessity for a new fire-proof building for the Army Medical Museum and Library. The following extract from President Hayes' message to Congress, in December last, is quoted: "The collections of books, specimens, and records constituting the Army Medical Museum and Library are of national importance. The library now contains about 51,500 volumes and 57,000 pamphlets relating to medicine, surgery, and allied topics. The contents of the Army Medical Museum consist of 22,000 specimens, and are unique in the completeness with which both military surgery and the diseases of armies are illustrated."

STATED MEETING OF THE STATE BOARD OF HEALTH. —NUISANCES NEAR NEW YORK.—The State Board of Health held its quarterly meeting at Albany, on November 9th. The most important report was that concerning the Hunter's Point stenches. The committee described the various measures that were being taken by manufacturers to lessen the nuisances. They concluded with a hopeful announcement of their belief that, by concentrated and united action on the part of the oil-refiners, they are conscientiously endeavoring to comply with the Governor's orders, and the great improvements made in the system of refining petroleum without offence to the people proves emphatically what was stated to the Board by the committee at a former meeting, viz.: that nine-tenths of the effluvium nuisances could be prevented by the proper application of what science has shown to be possible and practicable. The oil-refiners have made an excellent beginning, and the committee are of the opinion that they will continue to exercise the proper precautions, so that nuisances from this branch of industry will practically cease to exist. Do nuisances still exist, notwithstanding the improvement made by the refiners and in spite of the care exercised by them? There still remains the establishment of Edward Clark, who is engaged in the process of separating sulphuric acid from the impure material sludge. But this establishment, as well as that of Coe and others, will be obliged to close. Other industries producing various stenches, such as the bone-boiling and burning and fat-rendering establishments, are now working so that no official complaints concerning them have been transmitted by the Governor to the State Board.

" On the second day the President of the Board, Erastus Brooks, and the President of the Board were appointed a committee to represent the Board at the meeting of the Public Health Association, to be held at Savannah, on November 27th. Action was taken looking to the supply of applications for pure vaccine virus. The use of poisonous adulterations in confectionery was the subject of consideration by the Board. A report by E. Knickling, C.E., on the malarial nuisance along the abandoned Genesee Valley Canal, was submitted and ordered embodied in the annual report. Various petitions for aid in removing local nuisances were appropriately referred.

THE GARFIELD HOSPITAL SCHEME.—Mr. A. S. Solomons, Chairman of the Committee of Ways and Means of the National Garfield Memorial Hospital, has received the following letter from Mrs. Garfield:

MENTOR, O., October 31, 1881.

MR. A. S. SOLOMONS:

*Dear Sir*—Your letter of October 22d, giving an account of the action of the Memorial Hospital Committee, was duly received. I regard the project as a grand tribute to the memory of General Garfield, and one which would be to him most gratifying. The high character of those engaged in it is the best assurance of its accomplishment in the most worthy manner. It will be my pleasure to contribute to this object.

Very truly yours,

LUCRETIA R. GARFIELD.

THE NEW YORK MEDICO-LEGAL SOCIETY held a stated meeting on November 2, 1881. The paper of the evening was read by Dr. T. D. Crothers, of Hartford, Conn., and was entitled "The Trance State following Inebriety, and its Medico-Legal Relations." The paper is published in the present issue of the MEDICAL RECORD.

In the discussion which followed, the President asked whether tea-drinking in women could not produce the similar conditions of trance or a morbid nervous state allied to inebriety.

Dr. G. M. Beard said that there was plenty of room for difference of opinion as to what the trance conditions described by Dr. Crothers really were, and how they should be named. But he thought all could agree that there really were such conditions. The novelty in Dr. Crothers' paper lay in the fact that he assigned inebriety as the cause.

The speaker referred to a discussion in the Mental Section of the International Medical Congress, in which this subject was touched upon.

Dr. Beard had studied the class of classes described by Dr. Crothers, and he could not discover in them any relation to epilepsy.

Dr. E. C. Spitzka thought that there was absolutely nothing new in the paper of Dr. Crothers, and that it was not on a level with the science of the day.

The reasons for this view were given briefly and forcibly.

Brief remarks were made by other members.

A vote of thanks was tendered to Dr. Crothers for his paper.

THE SECOND ANNUAL INTERNATIONAL ANTIVACCINATION CONGRESS finished a four days' session at Cologne, on October 24th. Forty-five delegates attended. The following epitome of the views of the association, as set forth by a Dr. C. Pigeon, of France, will be read with interest on account of the extraordinary audacity of the propositions:

1. Small-pox, when rationally treated, is not relatively a dangerous disease. 2. Vaccination does not afford immunity against it, but, on the contrary (being itself an infusion of zymotic molecules), is an excitant of it. 3. Vaccination not unfrequently inoculates syphilis and other maladies much more dangerous than small-pox, as the virus is never free from the risk of such contaminations. The official returns of burgomasters in the cities of Liegnitz, Lubeck, Dusseldorf, Cologne, and other places, demonstrated the constant priority to attacks of small-pox of the vaccinated over the unvaccinated—a fact admitted to be true of infants by Dr. Thilenius, the leader of the provaccinators in the German Imperial Parliament.

Among other proposals approved by the congress was the petitioning of the various legislatures to make vaccinators responsible for the evil consequences attending the operation, which, it was believed, would at no distant day cause the practice to be abandoned.

The next congress is to meet at Berlin in 1882, during the sittings of the Reichstag.

BOGUS VETERINARY MEDICAL DEGREES.—The *Journal of Comparative Medicine* gives an account that is not without its humorous side, of various attempts to buy bogus veterinary degrees of the Columbia Veterinary College in this city. It appears that, immediately after the organization of that college, some four or five years ago, inquiries regarding the price of a diploma began to come in. The demand continued quite steadily, for the first few years, at the rate of one or two a month. Not meeting encouragement, it has of late fallen off. The amount offered for the diplomas varied, we are informed, from a shake of the hand to five hundred dollars.

We reproduce two of the letters, which represent very clearly the two prominent types of men who buy or want to buy diplomas, veterinary or medical. The first is from a Western man, of the class who "mean business," and to whom all the other considerations of life are a miserable and unhealthy efflorescence. He writes:

"Desire a diploma, but cannot spend time necessary to get one. Will give just one hundred and fifty dollars for the same—if we can deal; if not, all right. Anything you may say upon the subject will be strictly between us. Sincerely, etc.

"P. S.—You need not take the trouble to send me a lecture upon the immorality of my propositon; it would be wasted Am a Western man, and will do just as I agree, quietly, as it will be of service to me and cost you nothing."

The second letter is from a more callow specimen. The author would be much obliged if he could get a diploma for nothing. The epistle is a triumph of *naïveté* and phonetic spelling. Indeed, on the latter account alone it deserves an imperishable fame. It goes as follows:

"DER SIR: . . . . I want you to do me a faver if you Can posable & I will Reward you Sure when I come to the College I have Study vet Book for A long time & done good deal of doctern & had good Results in all my practis But when I go to Collect my Bills grate meny of our people will Say you haven not got no diploma & I wont pay you tel you git one So if you Can assit eny way pleas do it if you Can send me A diaploma by express Cod then I Can Collect wat is due to me & will Beable to Come to See you and give you a harty Shake hands I am poore & ned assistence I am young only 28

year old if this wont do Could I be examin by letter & git one pleas give me the best information you Can in Regard to it pleas answer Soon I want to do all I Can So I Can Come out to new york nex fall I think I Can bring one or to more Students when I Come. Yours truly."

The journal from which we quote remarks that, with such a general belief that veterinary degrees can be bought, it seems probable they are sold somewhere. It is proposed to investigate the matter further.

THE SAD END OF A BRILLIANT AND ACCOMPLISHED PHYSICIAN.—Dr. Adolph Goertz, a physician and an accomplished scholar, was found dead, November 6th, in the hallway of his residence, No. 23 Second Avenue. He was a native of St. Petersburg, where his father holds a high official position under the Russian Government. He received a fine education, and was graduated from the Imperial University in St. Petersburg with high honors. Choosing the medical profession for his sphere of duty, he was sent by the Government to finish his studies in the medical colleges in Berlin and Paris. He served in the Franco-Prussian war, and then entered the Russian service, where he reached a high position. He was obliged to resign, however, on account of his too liberal views. He came to this city about two years ago. He met with little or no success here, and finally became dissipated and was reduced to poverty. A number of German physicians, who admired his brilliant intellect and attainments, and pitied his forlorn condition, endeavored to help him, but without avail. They paid his rent for several months, gave him clothes, that he might make a respectable appearance, and loaned him surgical instruments to use in his practice. He pawned the clothes and instruments, and spent the money for drink. Within the few days previous to his death, Dr. Goertz seemed more cheerful than usual, and told his landlady that his prospects were becoming brighter, and that he would soon be in good circumstances. He had written a number of articles on cremation for a German newspaper, and had also written for the MEDICAL RECORD, and this occupation, he believed, would give him a living. It is believed that he committed suicide; but he was addicted to the use of hydrate of chloral, and he may have only taken an overdose. His father is very wealthy, but the son was too proud to apply to his family for assistance. He was an accomplished linguist, and spoke Russian, German, French, Italian, Spanish, and Japanese fluently.

DR. WILLIAM J. BLAND, of Weston, W. Va., has been appointed Superintendent of the West Virginia Insane Asylum, in place of Dr. Thomas B. Camden, who succeeded Dr. Hills, the first superintendent of the hospital, ten years ago.

THE FIFTY-FOURTH ANNUAL MEETING OF THE SOCIETY OF GERMAN NATURALISTS AND PHYSICIANS was held at Salzburg during the week beginning September 19, 1881. The meeting is said to have been a successful one, though not made notable by any great addresses or discussions.

In the Section on Pathological Anatomy, H. Chiari read a paper on "Atheroma;" Professor Klebs, a paper on "The Structure and Relations of the Blood-vessels of the Placenta, with Special Reference to the Pathological Changes in that Organ;" Professor Ziegler, of Zurich, a paper on "Several Cases of Epidemic Dysentery and the Relations of the Disease to Micrococci." Dr. Friedländer, of Berlin, presented some interesting statistics regarding hypertrophy of the heart in its relations to glomerulo-nephritis in children.

We give the tabulated statistics:

WEIGHT OF THE HEART IN CHILDREN WHO HAVE DIED FROM VARIOUS DISEASES. (The upper row of figures represents the age of the childen, the lower columns the weight of the heart in grammes.)

| 1. | 2. | 3. | 4. | 5. | 6. | 7. | 8. | 9. | 11. | 12. | 14. |

* Complicated with endocarditis.
† A case of glomerulo-nephritis of six weeks' standing.

A communication was made by Dr. Lösch, of St. Petersburg, upon the changes produced by chemical and thermal irritants to the mucous membrane of the stomach. The point made was that in the process of digestion the gland-cells go through changes very analogous to those seen in the earlier stages of an inflammation. It is inferred that the irritation of the nerves has something to do with initiating the cell-changes in inflammation as in secretion.

Dr. Aberle, of Salzburg, showed the skull of Paracelsus to the members of the section, and made some remarks concerning the history of that man.

Various microscopical preparations were shown.

In the Section for Internal Medicine and Skin Diseases, Dr. Lytten reported two unique cases of mycosis of the kidneys. The first patient was a servant-girl, who, when first seen, had apparently only a slight gastric catarrh. She was taken with a chill, followed by fever and slight jaundice. Then suppression of urine, œdema, and uræmia, with coma, convulsions, and death following, the latter occurring on the seventh day after the chill. Autopsy disclosed no special lesion, except in the kidneys. The tubules of these organs were choked and distended with micrococci, the condition being like that sometimes found in diphtheria or puerperal fever. A second and similar case was related. The cause of the development of the organisms was not known.

Dr. Strümpell, of Leipzig, read a paper on "Locomotor Ataxia," basing his remarks upon autopsical examinations of the cord in ten typical cases. His conclusions, from a study of the progress of the morbid changes in the cord, were that the disease was not a local one of the cord, but was a constitutional affection. This view aroused an extended discussion.

In the Section for Diseases of Children there was an extended debate on the subject of the proper

food for infants. The different kinds of milks, and of artificial infant foods were discussed, but nothing especially new was brought out.

In the Section on Gynecology, Prof. Kaltenbach, of Freiburg, advocated the extirpation of the fetal sac in extra-uterine tubular pregnancy. He thought that in this way danger of hemorrhage from the placenta was largely avoided.

Prof. Schroeder, of Berlin, made a communication upon the subject of the treatment of the pedicle in removing uterine fibroids. He advocated the plan of leaving the pedicle in, the operation being performed antiseptically. A discussion followed, in which Kaltenbach opposed and Baude supported Schroeder's view.

In the Section on State Medicine, the subjects of drinking-water, ground, air in dwellings, and the influence of soils upon the decomposition of organic substances, were taken up.

Absence of One Kidney.—Dr. J. Colburn Clement, of Haverhill, Mass., reports the following: "On September 24th, a young Irishman, J. K——, twenty-one years of age, was shot during a drunken row, and died on the 26th inst. An autopsy was made on the same day, under the direction of Medical Examiner Cogswell, and revealed the following anatomical peculiarity:

"On the right side the kidney was found in its normal position. I regret that the exact measurements were not made; however, it was fully one-third larger than ordinarily, and, in every respect, of normal appearance. On the left side we could find neither kidney nor anything resembling an attempted formation of that organ. The bladder was normal, and the right ureter intact, but on the left it was missing, there being only a small pit, or depression, corresponding to the opening in the right, and, leading from this, for about half an inch, was what appeared like a piece of cat-gut imbedded in the mucous membrane. This was, evidently, the remains of an attempted formation of the left ureter.

"The young man had been in America only a few months, and was hard at work as a coal-heaver. His employer speaks of him as the strongest man he had, and all who knew him considered him to be remarkably robust in his general health."

Notes on Vaccination, Based on the Results of Thirteen Hundred Cases.—Dr. P. G. Higgins, of Scranton, Pa., sends us some instructive notes regarding vaccination. Last winter, fearing a visitation of small-pox, all the school children of Scranton, to the number of seven thousand, were vaccinated. The result was most gratifying, for, though seven surrounding cities had cases of small-pox, in Scranton none occurred whatever.

In the vaccinations performed by Dr. Higgins, bovine virus was used, and crusts were considered the most economical and reliable form. Properly prepared, a medium-sized crust will suffice for two hundred vaccinations.

The lancet is considered a most objectionable instrument, especially for children.

"An excellent substitute for a vaccinator," he says, "and in fact a superior instrument, may be made by thrusting four or five coarse needles through a cork till the points are on a line, close together, say half an inch or so beyond the opposite side. This improvised instrument has the additional advantage of being equally available for scar and puncture, a combination which makes the neatest and most reliable operation."

"One hundred and twenty vaccinations in an hour may be performed with such an instrument. Three or four trials should be made in primary cases, supposing the vaccine does not act at first. In secondary cases, two trials are enough.

"For the malaise and fever of vaccinia, carbonate or sulphate of magnesia is of much service. Secondary vaccinations are generally milder in every way than the first."

In the thirteen hundred vaccinations, no death occurred, and not a single case of erysipelas. Four hundred of the number were primary, among which were four cases of vaccinia—one being quite severe. Twenty were quite slow in healing, three of which gave considerable trouble. Of the nine hundred not primary, five hundred were secondary, of which number two hundred were successful upon the first attempt, and about one hundred upon revaccination. In the remaining cases vaccination had been successfully performed twice, or oftener, and of these all but twenty-five failed. A much larger number were followed by simple inflammatory sores that ran a short course and healed up in a few days; but no case was considered successful without the characteristic zone of redness surrounding the crust, and fading out imperceptibly.

A Case of Peritonitis Caused by Rupture of Gall-Bladder.—Large Gall-Stone Impacted in Neck of Gall-Bladder.—Drs. McCauley and Leech, of Apollo, Pa., send us a report of the following case:

Mrs. K——, aged sixty years, mother of ten children, was taken suddenly ill August 9, 1881. She complained of severe pain in the right side, with nausea and slight vomiting. On inquiry, it was learned that for several days previous there had been soreness in that side, but it did not interfere with her following her usual household duties. Examination showed a small tumor, which could be distinctly felt, about two and one-half inches below the free margin of the ribs, and about three inches to the right of the median line. Bowels were constipated and slightly tympanitic. Pulse 125; respiration, 25; temperature, 102. Ordered opium, gr. j., every two hours, with hot fomentations over abdomen.

The tumor increased in size, the other symptoms continuing for two days. It then suddenly disappeared. The patient soon after had two very dark-colored passages, and, following these, dysenteric passages. The symptoms of peritonitis and intestinal irritation continued for a week. On August 18th the patient died.

Autopsy, three hours afterward, showed peritonitis pretty generally diffused over the right side of the abdomen, and as far to the left as the median line. There was about one and one-half ounce of clotted blood in the peritoneal cavity, near the cæcum. An enlarged gall-bladder extended down along, and adhered to the ascending colon, with fistular communication with gall-bladder entering the colon about one and one-half inch below the flexure. A small quantity of pus had found its way through the imperfect adhesion into the peritoneal cavity from the fistular opening. A gall-stone, one and one-half inch in length and about one and one-fourth inch in diameter, was found impacted in the neck of the gall-bladder, completely shutting off the passage of gall through the duct. The liver otherwise seemed normal.

The interesting features of this case are:

*First.*—The patient did not at any time during her illness complain of pain in the region of the liver.

*Second.*—The rupture of the gall-bladder by obstructed gall, and no jaundice that could be detected at any time by the closest observation.

*Third.*—The patient had better health for two or three years previous to her last illness than for many years before.

CIRSOID ANEURISM SITUATED IN THE OCCIPITAL, PARIETAL, AND MASTOID REGIONS.—Dr. Perez reports a case of cirsoid aneurism occurring in a woman, forty-six years of age, of good constitution, and without hereditary or personal history to explain the lesion. In the left occipito-temporo-parietal region, three or four flexuous and strongly pulsating arteries were observed, corresponding to the capillary ramifications of the posterior branches of the auricular, and of the branches of anastomoses between the occipital, its fellow of the opposite side, and the more anterior vessels. The largest branch followed the course of the trunk of the occipital, attaining its greatest diameter (two centimetres) above the insertion of the splenius muscle. Compression of the two arteries named diminished, but did not arrest pulsation in the tumor, and compression of the left common carotid produced the same result; pressure applied to both the common carotids, the auricular and occipital on the left side, and the anastomotic branches of the latter two with the vessels of the opposite side greatly enfeebled, but did not arrest, the pulsation. The bones upon which the tortuous arteries rested had been deeply furrowed; these furrows were readily recognizable by the touch. Cirsoid aneurism was diagnosticated. By its numerous anastomoses it formed an aneurismal plexus, probably with numerous communications with the intercranial vessels. In view of the dangers of surgical interference, treatment was limited to compression, and the family instructed what measures to adopt in case of rupture of these vessels.—*Rev. de Ciencias. Med. de Cat.*

HYGIENIC VALUE OF MIRTH.—In the *Popular Science Monthly* for August, 1881, Dr. Oswald speaks on this subject as follows: "Mirth has a hygienic value that can hardly be overrated while our social life remains what the slavery of vices and dogmas has made it. Joy has been called the sunshine of the heart, yet the same sun that calls forth the flowers of a plant is also needed to expand its leaves and ripen its fruit; and without the stimulus of exhilarating pastimes, perfect bodily health is as impossible as moral and mental vigor. And, as sure as a succession of uniform crops will exhaust the best soil, the daily repetition of a monotonous occupation will wear out the best man. Body and mind require an occasional change of employment, or else a liberal supply of fertilizing recreations, and this requirement is a factor whose omission often foils the arithmetic of our political economists.

"To the creatures of the wilderness affliction comes generally in the forms of impending danger—famine or persistent persecution, and under such circumstances the modifications of the vital process seem to operate against its long continuance. Well-wishing Nature sees her purpose defeated, and the vital energy flags—the sap of life runs to seed. On the same principle an existence of joyless drudgery seems to drain the springs of health, even at an age when they can draw upon the largest inner resources; hope, too often baffled, at last withdraws her aid; the tongue may be attuned to canting hymns of consolation, but the heart cannot be deceived, and with its sinking pulse the strength of life ebbs away. Nine-tenths of our city children are literally starving for lack of recreation; not the means of life, but its object, civilization has defrauded them of; they feel a want which bread can only aggravate, for only hunger helps them to forget the misery of *ennui*. Their pallor is the sallow hue of a cellar-plant; they would be healthier if they were happier. I would undertake to cure a sickly child with fun and rye-bread sooner than with tidbits and tedium."

PARSLEY FOR SUPPRESSING THE SECRETION OF MILK.—Mr. Martin claims (*Bulletin Général de Thérap.*, August, 1881) that, if the breasts of a nursing woman be covered with parsley-leaves freshly pulled, the application being renewed several times a day, as quickly as the leaves fade, the milk will cease to appear. This is an application which may be used when it is impossible to give purgatives or other remedies internally.

LOCAL MERCURIAL FUMIGATION.—This subject has lately received considerable attention in England. In the *Archives of Dermatology*, July, 1881, the following succinct account of it appears: Dr. F. H. Kane (*Dublin Journal of Medical Science*, November, 1874,) described and figured a simple apparatus by which the vapor of sublimed calomel could be readily, and with precision, directed on any desired region, such as the nose, mouth, pharynx, or skin. In 1872 (*British Medical Journal*) Surgeon Moffitt described a very similar apparatus, and renewed attention was directed to the subject by a correspondence in the same publication in 1880 (vol. ii.). Moffitt volatilized from three to five grains of calomel, and directed it by means of a stream of air, as in the spray-producers. Quite recently, Dr. Walter G. Smith read a paper on the results obtained by him since the publication of Kane's paper. He has used it frequently, and claims for it exceptionally gratifying and rapid curative results in similar cases to those in which iodoform is applicable; that it is painless even when directed on most sensitive surfaces; that it is easy of application, and capable of precision in use, and that it does not salivate.

THE CEREBRAL SYMPTOMS IN DYSPEPSIA.—In the *Progrès Médical* of May 28, 1881, M. Leven has collected a hundred cases tending to show the occurrence of cerebral phenomena in dyspepsia, the presence of which has hitherto been either little heeded or quite overlooked. Thus, he has seen patients suddenly struck down in the street with true apopletic attacks which last from ten minutes to a quarter of an hour. Such cases were believed to be epileptic, but M. Leven suggests that they were in reality simply dyspeptic, since the cerebral symptoms entirely disappeared when the digestive troubles had been cured. In dyspepsia the intelligence is unaffected, and there is never any mental disorder. Certain cerebral faculties may be altered, but the *ego* remains intact. This affection of the higher faculties, this weakening of the will, of action, of memory, and of the power of speech, may be readily observed. In some cases the patients are unable to determine upon an act, and they have to make a decided effort to perform what is generally an almost instinctive movement, as, for instance, to pick up anything that they have just dropped. In such cases the memory is impaired and speech is difficult, more especially after meals. The patients are melancholy, and suffer from cutaneous hyperæsthesia, a point which distinguishes them from the hysterical.

# Original Communications.

## POSITION OF THE EMBRYO IN THE FOWL'S EGG.

By JOHN C. DALTON, M.D.,

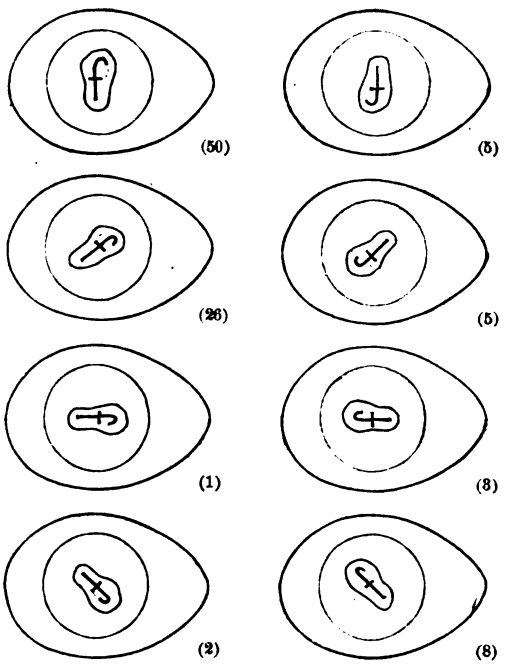
NEW YORK.

There is a singular difference in the statements of embryologists as to the normal position of the chick-embryo in the fowl's egg at the time of its first appearance and in the earlier days of incubation. It is agreed by all that it lies transversely—that is, with its long axis at right angles to the long axis of the egg. The discrepancy is in regard to the position of its right and left sides, as directed toward the round or pointed ends of the egg. According to Foster and Balfour,* "if the egg be placed with its broad end to the right hand of the observer, the head of the embryo will, in nearly all cases, be found pointing away from him." That is, the embryo lying upon the yolk with its abdominal surface downward, its right side is toward the round end of the egg and its left side toward the pointed end.

On the other hand, in the recent admirable work of Kölliker,† the relation of the embryo to the egg is described as exactly the reverse, namely, with its left side toward the round end and its right side toward the pointed end; and the text is illustrated, on pages 64 and 91, with a diagrammatic woodcut, borrowed from Von Baër, showing the embryo in this position. It is difficult to explain such a contradiction between observers of almost equal repute.

During the last summer I opened one hundred fowls' eggs, from the first to the third day of incubation. Of these, in four instances the embryo was longitudinal in position, with its head once toward the pointed end of the egg, and three times toward the round end; in twelve, it approximated the position described by Foster and Balfour, namely, with its right side toward the round end and its left side toward the pointed end of the egg; while in the remaining eighty-four its right side was toward the pointed end and its left side toward the round end. But, among the last-mentioned cases there were only fifty in which its position was exactly transverse in regard to the egg. In thirty-four it was more or less oblique; the head being inclined in twenty-six cases toward the pointed end, and in eight cases toward the round end. In the twelve cases, furthermore, where the embryo lay with its two sides in the position described by Foster and Balfour, it was exactly transverse in only five, being more or less oblique in the other seven. Taking the whole series together, the percentage of cases in which the embryo presented itself in these different positions was as illustrated on opposite column.

The position assigned to the embryo by Kölliker is, therefore, correct for the large majority of cases (eighty-four per cent.); except that it is not so rigidly transverse as might sometimes be inferred from the language of the books, but presents an occasional obliquity, most frequently toward the right. An increased deviation in this direction may shift the position of the embryo, in different cases, around the entire circle. But, notwithstanding this variation with respect to the exterior form of the egg, the relation of the embryo to the yolk and the embryonic spot is not necessarily altered. As the globular yolk is already fecundated at the time of its exit from the ovisac, and receives its envelopes of albumen and egg-shell afterward, the various positions of the embryo in the egg may be due to the manner in which the yolk is received into and transported through the oviduct. The egg receives its



ovoid form in the oviduct, from the unequal deposit of albumen in front and rear of the advancing yolk; and the segmentation of the cicatricula (the first step in the formation of the embryo) goes on within the oviduct, and is nearly or quite complete in the new-laid egg. The position of the embryo on the surface of the yolk is determined by the mode in which segmentation takes place in the cicatricula; and this is very possibly the same in all cases. But the yolk may vary its position in the fully formed egg, according to the way in which it entered the oviduct and there received its albuminous envelopes. Consequently, the embryo may vary from its usual position with regard to the two ends of the egg, without any change in its relation to the yolk or the cicatricula.

Successful Treatment of Diabetes Insipidus with Valerianate of Zinc and Tincture of Valerian.—Dr. R. Prior, of Brux, relates a case (*Lancet*) in which a patient suffering from diabetes insipidus was successfully treated with the above remedies. The patient, a man aged sixty-eight, was passing ten pints of water daily, and suffering from the usual accompanying disturbances. He was put upon valerianate of zinc, gr. ii., t.i.d., and tincture valerian co., ℥ jss., t.i.d. This gradually increased to gr. xii., t.i.d., of valerianate, and ℥ ii., t.i.d., of simple tincture. In the course of two months the bad symptoms had entirely disappeared, and six months later he was still well.

# CLINICAL OBSERVATIONS ON THE VALUE AND SAFETY OF ADMINISTERING LARGE DOSES OF THE IODIDE OF POTASSIUM IN THE LATE LESIONS OF SYPHILIS.

By M. H. HENRY, M.A., M.D.,

LATE SURGEON-IN-CHIEF OF THE STATE EMIGRANT HOSPITALS, NEW YORK, ETC.

In a recent discussion* on the value of the iodide of potassium in the treatment of syphilis, it was stated by one of those present—one who claims to speak knowingly on the subject—that sixty grains, divided into three or four doses, daily will do all we wish. This statement was challenged by a number of excellent practitioners present, whose experience led them to far different conclusions. I am induced to publish my own views, in a terse way, on this subject, because my experience has been exceptionally large for more than twenty years past, and, still more so, because I am enabled to give the results of some clinical observations of a practical character, unequalled by anything that I know of recorded in the works of therapeutists and syphilographers. The value of any medical article depends, in my judgment, on the quality of the cases and the integrity and brevity with which they are stated. Let me cite one extreme typical case, in which small doses of the iodide of potassium were utterly useless, and where extremely large doses effected an extraordinary cure, and where, in spite of the fears of some distinguished physicians (ten years having elapsed) there has been no injury to the kidneys or any other organs. The full history of this case was published† in January, 1872. My experience had then led me to administer large doses as the only means of arresting and absorbing gummy deposits, and in allaying the extreme symptoms of the later lesions of syphilis. The result is the best and most accurate testimony in support of my conclusions.

Case.—Mr. ——, gentleman, twenty-five years of age, had, when in good condition, contracted syphilis in May, 1868. He consulted a surgeon of this city, who gave him small doses of mercury for a short time, treated the case lightly, and assured him he would have no further trouble with it. In the following August he had a severe fistular syphilide and sore throat. At this time I was consulted. Under a mercurial course of treatment, and local applications to the throat, he soon improved, and the eruption disappeared. He spent the winter of 1868-69 in Texas, and enjoyed excellent health. In December, 1869, he sailed for Cuba; remained on the island until May, 1870, when he sailed for Southampton. In all his letters to his friends he stated that he was enjoying perfect health. On leaving the ship at Southampton, he, with difficulty, found his way to a relative's house in London. Here he was attended by Dr. Edward Meryon, a distinguished English practitioner, assisted by Dr. George Burrows in consultation. He sailed for New York on the 27th of July, 1870. He was under the care of these physicians from June 8th until the day he sailed. From the history furnished by Dr. Meryon, he reached London in a state of "mental incoherence," and "was suffering from congestion of the brain and a generally disturbed circulation." He soon "fell into a state of restless stupor, with a hot skin, quick, weak pulse, injected conjunctiva, widely dilated pupils, not readily answering to light, and he was very deaf." The physicians had no knowledge of his having had syphilis. Dr. Burrows concluded he had suffered from a sunstroke on the voyage from Cuba. Hearing accidentally of his condition in London, I furnished a relative with a history of his case. From June 6th to July 7th he was treated with calomel purges, mustard poultices, and blisters applied to the nape of the neck, morphia or hydrate of chloral at bedtime, and the syrup of the hypophosphite of iron and liquor strychnia three times a day. During all this time the mind remained in about the same state. Dr. Burrows declared on June 30th that an extensive part of the brain must be disorganized. On receipt of the information I furnished, it was decided to administer small doses of the iodide of potassium, but there was no marked alleviation of the symptoms.

Dr. Meryon writes: "From all that I have been able to observe, and from the persistence of the mental phenomena, I have arrived at the conclusion that there is structural change in the cerebral substance round about the optic thalami, extending toward the surface of the cerebrum, and close upon the tractus opticus, for every now and then the sight is obviously affected. Were there disease more in front, and implicating the corpora striata, motion would doubtless be affected. If in the cerebellum, either there would be loss of co-ordination of muscular motion, or some disturbance of the genital organs, or sickness, of which none exist. If about the crura cerebri, the muscles of the eyes would be affected; if in or about the pons Varolii, some facial disturbance would present itself; and if in the medulla oblongata, some affection of speech, deglutition, or respiration."

On his return home he began to fail badly. Dr. D. Tilden Brown was consulted, and advised that he be placed under my care.

On September 4th I first saw him after his return from Europe. Although I had known him very well indeed, he did not recognize me. In response to my questions, he answered incoherently and foreign to my interrogations. He seemed to have lost his mind entirely. He stood up with great difficulty, and as he attempted to walk his knees gave way and he swayed from one side to the other. He showed a fear of falling, and only maintained the erect posture with a great effort. As he stepped forward he was unable to lift his feet—he dragged them along. He was as stout as when I saw him last, but his flesh was "flabby." There was paralysis of the whole of the right side of the face, with considerable distortion. The right cheek bulged out, and the mouth was constantly open; the tongue turned to the right and hung forward. There was mydriasis of both eyes. The left pupil responded to the influence of light; the right did not in the slightest degree. There was paralysis of right oculo-motoris nerve, with complete ptosis of the right eyelid. His appetite was bad, and deglutition very imperfect. He retained food in his mouth for hours; although unable to swallow, it did not occur to him to remove it from his mouth. His sight was very bad—he could not read or even tell the letters of large print. His whole look and manner gave the impression that he had entirely lost his mind, in fact was suffering from all the symptoms and many indescribable features that are known to syphilographers in the term *l'hébétude*. He was at this time in the habit of passing his fæces and voiding his urine involuntarily. I ordered a generous diet, a little wine, and thirty grains of

* New York Academy of Medicine, October 20, 1881.
† American Journal of Syphilography and Dermatology.

the iodide of potassium to be given three times during the day, and thirty grains of the bromide of potassium to be given at bedtime. I also insisted on the necessity of the greatest care of his person and general wants.

On September 6th there was not the slightest change in his condition. Increased the amount of potassium to four thirty-grain doses daily. Continued the bromide at night.

September 7th.—There seemed to be a little less paralysis of the face and less fall of the right eyelid. His speech and articulation was a little better.

September 8th.—Was a little better; still voiding his urine involuntarily. On examination found it 1023; no albumen.

September 9th.—Dr. W. H. Van Buren saw the case with me. The iodide of potassium was increased to five doses daily. His appetite improved, and he slept much better.

September 11th.—The only noticeable change was that he was a little more cheerful. Since he slept well I discontinued the bromide of potassium at night, and added another dose of the iodide—making one hundred and eighty grains of the potassium daily, in six doses.

September 12th.—He complained of a little difficulty in digesting his food. Ordered five grains of pepsine and five grains of bismuth before each meal.

September 13th.—Much better in general appearance. Face decidedly improved. Eats well and sleeps well. Digestion much better.

September 14th.—Still improving. Answered questions more intelligently; conversed in the morning with comparative ease. Has no control over the bladder. Sleeps well and eats well. No ill effects of any kind from the use of the iodide of potassium. Increased the amount to seven doses, making two hundred and fifty grains daily.

September 17th.—Facial paralysis much less. Less deformity about the mouth. Improved in intelligence. General condition much better. Ordered the medicine to be taken every two hours—taking two hundred and fifty grains of the iodide daily.

September 20th.—Sits up all day. Has no control over the bladder. In general apearance is much improved. Answered questions more intelligently than he had done for some months. Taking two hundred and eighty grains of the iodide of potassium daily.

September 21st.—Went out for a ride. Treatment continued.

September 26th.—Very much improved, mentally and physically. Rides out every day. Walks better. Can read slowly. Mydriasis of left eye entirely disappeared. Right eye a little better. Treatment continued. Examination of urine showed slight deposit of crystals of oxalate of lime. Spec. grav. 1030.

October 3d.—There being little or no improvement during the last three days, and as he showed great tolerance of the iodide, I increased it so that he is taking three hundred grains daily. From this time until October 19th he was gradually improving. Walks out every day. Eats well and sleeps well. Reads better, and sits up in the evening and plays cards, such as whist and cribbage, well. Has control over his bladder, and shows a great improvement in his general intelligence. His sight being very much impaired (October 19th), my friend, Dr. H. D. Noyes, was kind enough to see him with me, and the following is the result of his examination:

"There is divergent strabismus, but the attempt to investigate the condition of the muscles with any care is impossible, on account of the great amblyopia and the clouded state of his mind. He answers questions very slowly, and his apprehension is extremely limited. His face is pale and has a vacant expression.

"The right pupil is slightly dilated, but contracts when the eyes attempt to converge. The left pupil normal.

"Vision in each eye $\frac{2.0}{200}$. Reads Snellen 5 at eight inches. Visual fields could not be defined. Color perception not tested.

"By ophthalmoscope, right eye: media clear, emmetropia; optic nerve unnaturally white, border sharply defined, and heavily marked with pigment; its tissue opaque; its surface not elevated; the veins large, arteries of usual size; deficiency of small vessels.

"The retina exhibits a glistening, clouded infiltration, which makes it appear like watered silk. The exudation occupies the depth of the membrane, and extends over all the central portions of eye-ground. There are no apoplexies nor spots of exudation.

"In the left eye the media are clear and refraction emmetropic. The optic nerve is congested, looks as much too red as the other optic nerve too white. Arteries and veins are of the usual size and appearance; the retina hazy and infiltrated as in the other eye.

"The lesion in this case is evidently neuroretinitis, and the appearances favor the presumption of a process coming down from the brain by continuity of tissue, not the occurrence of strangulation of the head of the optic nerves from pressure on the return circulation. The absence of decided elevation, and the sharp limitation of the right optic disk, are arguments for this opinion. In the right nerve the acute inflammatory stage had passed, and there remain the connective tissue and atrophic degeneration of nerve-fibres. This would imply that the left eye was attacked after the right, or may have been more severely inflamed, because in it the symptoms of hyperæmia are decided. The lesions seen by the ophthalmoscope stand in full accord with the other symptoms, indicating serious brain trouble."

October 24th.—Sight very much improved. Can read the large print of newspapers tolerably well. Walks much better, and, when standing, is much steadier in his knees; related plainly and without hesitancy what he had done the day before. Still suffers from incontinence of urine.

October 28th.—Improving daily. Looks decidedly better. General perceptive qualities much more acute. Can walk half a mile without fatigue. Memory much better. Converses rationally on ordinary topics. Realizes his condition perfectly. His appetite is good. Has no desire to sleep during the day, but sleeps well during the night. Continues to take the full amount of the iodide of potassium (300 grains), as well as the quinine and iron.

November 1st.—Gaining in strength. Treatment continued.

November 4th.—Called at my office; looks very well. Has lost almost entirely that dull, vacant look. Memory still improving. General intelligence steadily returning. Walks a mile without fatigue. From this time he went on gradually improving; he spoke of his visit to Havana being like a dream. In the early part of January, 1871, he took very little of the iodide of potassium, and in February discontinued it entirely. In March he

was, to use his own words, quite himself again, with this exception—his sight was still imperfect. He is able to walk to his father's office every morning, a distance of three miles, and walks up in the evening without feeling fatigue.

During the summer he spent a portion of his time in the country, and returned to the city, apparently as well as ever, November, 1871. The only difficulty from which he now suffered being his visual power and capacity, I again called in my friend, Dr. Noyes, and availed myself of his skill and experience. The following is the result of his examination:

"November 24, 1871.—Mr. —— examined again. The right pupil, which was formerly dilated, is now of normal size and behavior, while the left pupil is enlarged, although contractile. The movements of the globes are normal; does not have diplopia. Vision in each eye $\frac{20}{70}$. Reads Snellen 1¼ at five inches, with each eye or with both.

"To the ophthalmoscope the right nerve appears pale and bluish white; edges a little indistinct; very deficient in small vessels. Arteries small, veins large, no pulsation. Left optic nerve, which thirteen months ago was congested, is now of a bluish white color, its border strongly defined and pigmented; has neither elevation nor depression. The small vessels in horizontal meridian very few. The adjacent retina clear, except above nerve is a glistening streak of connective tissue, and at the macula the retina has a glistening bluish or steel-colored reflex, as if due to connective-tissue formation.

"The optic nerves, it is thus seen, have passed through the period of active inflammatory congestion to the state of white atrophy. Much of the nerve-tissue has survived the ordeal, and being now relieved of the inflammatory hyperæmia and accompanying infiltration, vision has advanced from $\frac{1}{10}$ to $\frac{2}{7}$."

This was an extremely interesting case of dementia and hemiplegia due to syphilis. Small doses of the iodide of potassium failed to effect little, if any, improvement; with the increase of the large doses there was a marked daily change for the better. There was, beyond any question, extensive and diffused gummy deposit within the arachnoid at the base of the brain, but mainly on the right side. From my later experience—during the past ten years—in many cases equally interesting, I am satisfied that small doses would not have secured the good results. Large doses are essential to the absorption of gummy deposits and the hard induration due to syphilis. This I have found to be the rule in all old and inveterate cases. In the hard induration of the os and cervix uteri due to syphilis—to which I called attention some years ago—small doses of the iodide of potassium failed to effect any perceptible change in the parts; as the doses were increased the improvements were most marked. In many of the old and inveterate forms of the later lesions of the disease, it is, I am satisfied, absolutely necessary to saturate the system with the drug to derive the full benefit. There need be no fear of iodism; it is seldom, if ever, seen in the late lesions. Should it be induced, a cessation in the use of the drug for a few days will correct the annoyance. The preparations of iodine seem to have an affinity for the gummy and hard œdematous deposits of syphilis. In the case of dementia and hemiplegia, the patient took three hundred grains daily for more than eight weeks, and with the disappearance of the syphilitic symptoms, he gained steadily in his general health and in flesh. To obtain the best results in the use of the iodide, it should be taken thoroughly diluted—each dose in a glass of water. If there is any nausea, a little compound tincture of bark, or an infusion of columbo, may be added. The drug is readily and perfectly absorbed when taken in a good quantity of fluid. A little of the wine of pepsine, or a small quantity of lacto-peptine, will assist absorption. I have frequently found the latter of great service where the stomach has been, at first exhibition, somewhat intolerant of the drug. The fear of sclerosis of the kidney from the use of the iodide of potassium in severe forms of syphilis, is a phantom that has been the torment of some minds for a long time past. It may result from syphilis, not from the use of the iodide of potassium; on the contrary, the use of the iodide lessens, if it does not entirely remove, all possibilities of such a probability. In conversation, a few days ago, with the patient whose case I have quoted as a typical one of dementia and hemiplegia, he assured me he was perfectly well, and had enjoyed good health since I discharged him, cured, nearly ten years ago. He is stout and hearty, and is in full possession of all his faculties, and has been for many years attending to his business. He bears no evidence of any syphilis, and certainly none of any disease of the kidneys.

It is a curious coincidence that his father, a gentleman of over seventy years of age, who never had syphilis, and who, from his own account, never took a dose of the iodide of potassium, is now under my care, a victim of Bright's disease. He was seen in consultation about a year ago by Drs. Van Buren and Agnew, who confirmed my diagnosis. In two of the three cases of induration of the os and cervix I attended over ten years ago,* I had an opportunity, during the past summer, of confirming my impressions. They were both in excellent health. I frequently meet patients who were under my care as far back as 1864, and who, in the course of treatment, took very large doses of the iodide. They are invariably doing well, and bear no evidence of disease of the kidney or any lesion of syphilis. Indeed the greater my experience the more I am impressed and convinced of the curability of syphilis under judicious management and a thorough course of treatment.

The loose and flippant statements of many *soi-disant* experts regarding the value and efficacy of many therapeutic agents, has too often tended to excite distrust of the value of many valuable drugs.

I am fully convinced that the so-called expectant plan of treatment has, in many cases, caused more injury to suffering humanity than the so-called heroic treatment in many forms of disease. I am led, from many circumstances and observations, to think that many of those who denounce the use of good, sound, impressive doses of medicines, have more the element of self than of science in the motive; a desire to impress the uninitiated with a feeling of the wonderful conservatism and judgment exercised by the medical iconoclast. The most instructive of all clinical observations is to ascertain, at a later period, the results and value of certain courses of treatment.

Static Electricity furnishes a most valuable means for the relief of impotence, according to Dr. R. A. Vance.

* Reported in American Journal of Syphilography and Dermatology, October, 1874.

## EFFECTS OF THE ABUSE OF THE SEXUAL INSTINCT IN FEMALES.

By WILLIAM A. DAYTON, M.D.,

NEW YORK CITY.

The accordant testimony of all writers on the perversion of the sexual agency proves, beyond the possibility of doubt, that many of the special diseases of women originate from violation of the function of coition. A thorough treatise on this subject, at once broad and important in its varied aspects is, however, wanting in gynecological literature; and I venture the following statements, which may prove of service by inviting a line of investigation that is worthy of greater consideration than has yet been accorded to it.

Professor T. Gaillard Thomas ("Diseases of Women," p. 649) says: "The coming decennium will, I feel convinced, prove that in many cases disease of these most important organs (the ovaries) in the female economy is the source of many ills now attributed to that less important viscus, the uterus." Again, under the head of treatment for ovaritis (p. 650), he says: "Sexual intercourse should be limited as far as possible." Intercourse is here interdicted, as it aggravates the existing irritation. We know that the *complete* sexual act (*i.e.*, terminating in orgasm) is a normal stimulant to the ovary or ovaries; but when abused, the excessive stimulation must result in pathological conditions.

The phenomena accompanying the exercise of the sexual instinct in the female have gradually been brought to light by careful observers; and now but one point remains to be demonstrated, viz., the rationale of orgasm. Assuming merely that the sexual instinct in all its phases is designed for a definite *use*, I propose to show that *abuse* of this instinct will induce: 1st, inflammatory changes in the ovary, beginning as a simple congestion; and 2d, abortion. The latter resulting either from reflex irritation originating in the ovaries, or from (what is probably the most common cause) frequent erection of the uterine tissues. That erection of an impregnated uterus can occur without destroying the adhesions of the ovum, is illustrated in all cases where the sexual instinct is exercised moderately, and utero-gestation continues to full term. It is, therefore, abuse alone that induces abortion.

### DIFFERENTIATION BETWEEN USE AND ABUSE.

Within the range of perfect health there is a standard for all the functions of life. When stimulant powers are applied in *due* proportion, vigor, tone, and health of the organs is the result. Here is suggested the argument that "each man is a law unto himself," nay, and each woman as well. Still, these functions can only be performed in a *due* degree. To say that they can be performed in an excessive degree, within the limits of health, is as great a contradiction in terms as excessive virtue or excessive joy—the one is vice, the other pain. The standard, then, consists in a pleasant, easy, and exact use of these functions. Applying this idea to the generative function in women, we find that the perversion of the sexual instinct in girls, and the too frequent indulgence in the complete act in married women, are abuses which nature can not and does not tolerate. The fact that these abuses are so common, and continued to such lengths with concealment, that, coupled with the testimony regarding the increase in diseases of women, I am not surprised at Professor Thomas' prediction as above quoted; and I fully believe that the ovaries *will* be found to be the seat of disease in most instances where the history of solitary or sexual excesses is obtained. The development of the nervous system in girls is marked by certain peculiarities at the time of puberty, which are due to the extensive change occurring in the generative tract, whether that time be hastened or protracted by varying causes. The factors comprising the change are: 1st, increased vascularity; 2d, increased dimensions, together with the awakening of the nervous functions, thus producing, respectively, local warmth, local weight, and local sensibility; conditions that are favorable to that important change "from the passive to the active condition." (*Vide* Harvard Prize Essay: Mary Putnam-Jacobi.) In this healthy, "active condition" of these parts, abuse in either way specified induces pathological changes, ofttimes of the most alarming and obstinate character. Perhaps the latest views bearing directly upon this subject are presented by Dr. G. M. Beard in the Medical Record of February 19, 1881. Speaking of "sexual neurasthenia in women," he says, "Woman is man, pathologically." In the three cases cited, "ovarian tenderness" was a prominent result of self-abuse. This result of abuse is entirely in accord with other observations on the subject as well as my own; but I would take issue with the doctor on the first statement. Prolonged sexual or other abuse in men impairs the function of the semeniferous tubules, and impotence rapidly ensues. In women, on the contrary, the ovaries are abundantly supplied with primitive ova, which, according to De Graaf ("Buffon's Nat. Hist.," vol. iii., p. 41), "increase with age and intercourse with men." Hence a case of acquired impotence in a female has yet to be recorded. Premature decline and death, as illustrated in the cases of prostitutes, is the result of abusing the sexual instinct, rather than impotence.

Without doubt, complete ovulation is a prerequisite to menstruation and conception; but that the height of sexual excitement, orgasm, necessitates the escape of an ovule, must be an open question until actual demonstration settles it. The only fact we know in this connection is that women, normally, are most prone to excitement at or about the menstrual epochs. In women, physiologically perfect, an ovum escapes from the ovary once every twenty-eight or thirty days. Prof. Charles D. Meigs enunciated the opinion that the development of the Graafian follicles even continued throughout pregnancy, which opinion has been confirmed by Dr. Slavjanski (*Med. Central. Zeitung*, October 30, 1878). It would therefore appear that the process of ovulation is never at rest from "puberty" until the "change of life." It is a process of invariable occurrence in health during these limits, and, like any other physiological function, it can be so stimulated as to induce abnormal cell development and other changes in the ovaries. (See article on "Ovaritis," by John Williams, M.D.: Reynolds, vol. iii., p. 851.)

Regarding the escape of ova, there can be but one opinion. The only secretion found in the ovary is the liquid of the Graafian follicles, and it is this liquid which determines, for the most part, "the rupture." When the follicle ruptures the ovum is said to be "ripe;" but that an ovum can not escape without the presence of this secretion cannot be denied in the light of the latest observations. Hence, Coste, as quoted by Flint, says: "I believe there are cases in which, *in the absence of suffi-*

*ciently favorable conditions* this distended vesicle cannot accomplish this end (rupture), and, as in mammals, may remain stationary or be entirely re-absorbed." We learn, also, from the experiments of Coste, Flint, *et al.*, that "coitus will precipitate the rupture of a ripe follicle." Coitus can effect this in but one way, viz., by inducing a determination of blood to the ovary, whereby the only process of secretion in that organ is augmented. This congestion results from two causes; 1st, from erection of the uterus and the Fallopian tube; and 2d, from the squeezing action of the fimbriated extremity on the ovary. (*Vide* Ramsbotham: "Process of Parturition," p. 65.) We can, therefore, readily understand that *when the ovaries are over-stimulated they will over-secrete;* but, be it remembered that over-stimulation cannot occur save that a woman exercises the complete sexual act, and that to excess.

In taking up the subject matter—abuse of the sexual instinct—we are led to note: 1st. What constitutes the complete sexual act in the female? 2d. What is the condition of the intra-pelvic organs and nervous system during and subsequent to the act? 3d. What are the effects of too frequent repetitions of the act?

We recognize that for the normal mechanism of any function, the organ or organs concerned in it must be physiologically perfect; and, as regards the generative functions, we must remember that they, perhaps, are pre-eminently influenced by any derangement in the economy. The sexual instinct is not experienced until after the establishment of menstruation, and from that time the hitherto "dormant flood of passion" is developed gradually to perfection on physiological principles and for physiological ends. This we cannot doubt when we take into consideration the design of the organs of generation. Note here the distinction between "man and the lower animals" in the aptitude for intercourse. While a discussion of this subject is here uncalled for, a practical point is suggested, viz., that the complete sexual act may be exercised in the human female at times other than about the menstrual periods.

The first question under consideration is, *What constitutes the complete sexual act in the female?* I do not know that this has ever been concisely and satisfactorily answered, but the reply is summed up in four words, viz.: excitement, erection, orgasm, and impregnation—nihil plus, nihil minus. This is easily illustrated in any case where a single concourse results in pregnancy. In the orgasm of masturbation, I believe the fimbriated extremity of the Fallopian tube, after its erection, grasps the surface of the ovary, as in the former case.

Anticipating the question of conception without excitement, erection, and orgasm, I quote from Prof. Montrose A. Pallen's paper (*American Journal of Obstetrics*, July, 1880), as follows: "Many women contend that they have no orgasm, which cannot take place without erection, yet such may ensue without consciousness upon their part, because of the faulty development or distribution of the sensory nerves. The mere friction contact of the male organ with the uterine cervix is sufficient to provoke response in the erectile tissues" (uterine, salpingial, and peri-salpingial), "just as a full bladder or loaded rectum may produce it in the male during sleep or intoxication." It is not women thus constituted, however, who suffer from abuse. When the instinct is not perceived it certainly cannot be abused; therefore the complete act requires, as Professor Pallen justly observes, "a kind of education, as it were." The first attempts are usually incomplete, in that several uterine contractions occur without "the climax." It is for this reason that Spencer Wells argues "that in every seven fruitful marriages, delivery takes place in but four of them prior to the expiration of eighteen months; while Pueck, for the same reason, found that in ten fruitful marriages, but five of the women were confined by the end of the first year. I have here collected three cases bearing upon the subject, which are of interest. The first is a case of Dr. Beck's, quoted in Flint's "Physiology," p. 890. The patient was a very erethistic female, and was under treatment for uterine prolapse. Dr. Beck "swept the right forefinger across the cervix twice or three times, when almost immediately orgasm occurred. The os opened to the extent of fully an inch, made five or six successive gasps, drawing the external os into the cervix each time powerfully, and at the same time becoming quite soft to the touch. All these phenomena occurred within the space of twelve seconds time certainly, and in an instant all was as before; the os had closed, the cervix hardened, and the relation of the parts had become as before the orgasm." The woman was "positive" that the sensations produced were the same in quality as they were during coition. For evident reasons this is not a test case. It is of interest merely in proving that erection of the uterus is an essential factor in the complete act, and the term "orgasm" is, I think, here misapplied, as twelve seconds is entirely too short a time for the "crisis" to supervene.

The second case occurred in the hospital practice of Dr. Paul F. Mundé. A Swedish woman, aged twenty-six, while undergoing an examination, was accidentally touched on the cervix with a uterine probe. She immediately became excited, when Dr. Mundé repeated the cervical friction, at the same time commanding her to "keep still." Intense sexual excitement was betrayed in an unmistakable way, and the cervix contracted at each touch of the sound; but her sudden rising, with the speculum *in situ*, prevented further study. This case proves "the contractions" as in the former, but it shows more, viz., that orgasm had, in all probability, not occurred, and that further stimulation was necessary to provoke it. The developments in the third case were as follows: A German girl, aged twenty-two, was addicted to excessive masturbation. At the time of her examination for anteversion, two weeks—or strictly, thirteen days—had elapsed since her previous "period," and seven days since the last "abuse." She cautioned her physician against "too much fingering," as she was "easily thrown into an uncontrollable condition." With all possible care the forefinger was introduced and the cervix touched, when intense "desire" began to be manifested. A continuance of the touching was solicited. In not less than *sixty seconds* the cervical contractions began, succeeding one another rapidly and regularly for fully *another minute*, when, after a deep sigh, they ceased, and the cervix was normal again, save considerable turgidity. A good sized speculum was then introduced, the cervix was again rubbed, even the clitoris was touched, but without response, and the examination was completed. In this case the ovaries were enlarged and very sensitive.

The lassitude which follows the complete act is very characteristic, incapacitating a woman for some time; while the mere uterine contractions may recur indefinitely in response to the necessary stimulus,

until the "crisis" occurs. Every close observer cannot fail to note this fact.

As we have seen, there is no doubt that the rupture of a Graafian follicle does occur as the crisis of the sexual act; we know that crises can occur at times other than about the menstrual epochs, and here is presented the important question: Is the rupture of a Graafian follicle essential to orgasm? Even supposing such to be the case, this would not account for the real source of enjoyment at the "crisis;" for we know that ovulation *per se* is never conducive to any such effect. The crisis is, in all probability, due, after the uterine contractions, to the spasmodic movement of the fimbriated extremity of the Fallopian tube toward the congested ovary. The process is thus described by Ramsbotham, p. 65: "By its own inherent muscular power, the Fallopian tube, under the venereal orgasm, erects itself somewhat like a snake raising its crest. By the same inherent muscular power it directs itself to the ovarium, it widely spreads its fimbriæ, expands itself upon the external surface of the gland, closely embraces it, and squeezes from it the contents of one of the follicles of De Graaf." I have recorded two cases which sustain this theory. The first, Mrs. I. W——, a patient of mine, ceased to menstruate at forty-four and a half years of age. Her husband informed me that she enjoyed coition as much as ever, but the desire was never manifested until provoked. The second case is the wife of a physician, in whom the menopause occurred on her forty-sixth birthday. The doctor volunteered the information, in a conversation upon the subject, that his experience was entirely in accord with the case just cited.

THE CONDITION OF THE INTRA-PELVIC ORGANS AND THE NERVOUS SYSTEM DURING AND SUBSEQUENT TO THE ACT.

As long ago as 1846, Litzmann (Flint's "Physiology," p. 891) observed that the uterus erected itself, as the result of stimulating it, during an examination; and other trustworthy observers have seen the same condition since under similar circumstances. Ramsbotham ("Process of Parturition," p. 65), as above quoted, asserts that the same inherent power of erection exists in the Fallopian tube. We know, further, that during "the act" all the erectile tissues in the vagina are called into play; so that, recalling the physiological causes of erection, we can readily understand that at the "crisis" the entire generative tract is in a state of congestion, and that —normally—for a definite end. When the process terminates, the hyperæmia subsides, and the parts regain their former state. Again, the nervous system is called into play; and it is this operation of the nervous functions which gives rise to the lassitude succeeding "the act." It is, of course, impossible to determine the time required for a normal congestion of these parts to subside. The rapidity with which these organs and the nervous system regain their previous condition must depend upon the vigor, etc., of the subject. But recalling how slow the process of reparation is after the rupture of Graafian follicles, may not this be an argument as to the danger of over-stimulating the ovary?

THE EFFECTS OF TOO FREQUENT REPETITIONS OF THE COMPLETE SEXUAL ACT IN THE FEMALE ARE LOCAL AND CONSTITUTIONAL.

In reviewing the subject of "intemperate intercourse" as a source of disease in women, we are impressed by its frequent mention by eminent authorities. In Prof. T. Gaillard Thomas' work, variously interpreted, it is mentioned as a cause of acute endometritis (p. 230), chronic cervical endometritis (p. 240), chronic corporeal endometritis (p. 258), areola hyperplasia (p. 293), granular and cystic degeneration (p. 310); also as a cause of pelvic hematocele (p. 492), periuterine cellulitis (p. 458), etc. In an article on "Inflammation of the Ovary" by Dr. Williams (Reynolds, vol. iii., p. 853) "excessive sexual indulgence" is stated as being a prominent cause of ovaritis. Again, in an article by Dr. Priestly (ibid., p. 784) on "Metritis," too frequent indulgence in "sexual intercourse" is pronounced "a potent cause of these affections." Thus we might go through a long list of standard authors, adducing evidence enough of positively evil results from abuse of the sexual instinct; but, perhaps, the most common effects of this abuse are ovaritis (in one of its forms) and abortion.

This day (October 29, 1881), an abstract from a paper on "Ovaritis," by Prof. Vedeler, is published in the MEDICAL RECORD, to which I wish to refer. The pathology is admirably stated thus: "That as the inflamed ovary is irritable, and larger than normal, and, as a rule, dislocated and fixed, it is easier to feel than the normal one. The size of the inflamed ovary is, in the ordinary forms, about that of a common apple; in chronic cases, that of a walnut, chestnut, or (most frequently) an almond shell; the surface is generally smooth, the consistence elastic. In the larger ovaries can be felt distinctly small elevations, supposed to be inflamed and hypertrophied follicles." Of the fifty cases under his observation "excessive coitus was not met with as a cause." Thirty-eight per cent. were caused by gonorrhœa. But mark the following statements. "Over thirty per cent. were sterile," and "in eighteen of the fifty cases no cause could be found." As regards the sterile women, no wonder that "excessive coitus" was not assigned as the cause of their ovaritis; and perhaps this review of the subject of abuse may point to the cause in the eighteen odd cases!

All cases of ovaritis, whether concealed* or apparent, caused by abuse of the sexual instinct, must begin as a simple congestion in or about the ovary—in other words, as the recognized first stage of inflammation, upon which a subacute or an acute form may supervene, according to the degree of application of the exciting cause. Two elements in the complete sexual act can induce this congestive stage. First, erection of the Fallopian tube and perisalpingial tissues. Second, the action of the fimbriated extremity on the periphery of the ovary. This congestion is normal at seasonable times; but when encouraged by violation of the province of coiture, pathological conditions must be the inevitable result. See, in this connection, "Prolapse of One or Both Ovaries from Sympathetic Engorgement of the Ovaries." Hartshorne (Reynolds, vol. iii., p. 854).

That the effect of frequent erections of the uterus will induce abortion, is readily demonstrated in the familiar cases of prostitutes. A careful analysis of these cases proves that it is not any form of metritis or ovaritis, nor is it, so much, the peculiar life these women lead, which induces, primarily, general debility and "neurasthenia," but the extent of abuse to which the generative organs are subjected. In cases of endometritis, etc., in this class of patients, the elements of conception are not retained at all, and even when the uterus is normal, containing an

* See Reynolds, vol. iii., p. 851.

impregnated ovule, the latter is readily displaced by frequent erections of the organ; while the tendency to abort increases after each displacement.

Unfortunately the sexual instinct in polite life is too little thought of as a source of irritation; whereas it is not infrequently abused, often furnishing a practitioner with mysterious cases of the origin of which he knows nothing, and into which it might be considered, by interested parties at least, improper to inquire. The fact that many of the diseases of the generative tract, together with abortion and various constitutional disturbances, are the direct results of abuse of this instinct, is sufficient to warrant careful inquiry in all cases; and we should be prepared to preach moderation or total abstinence as occasion might demand.

I have recorded nine cases of abortion between the first and third month, which could be easily traced to abuse of the sexual instinct. In six of the nine cases impregnation occurred between seven and ten days prior to the anticipated menstrual flow. The reliability of my memorandum is sustained by the fact that the husbands in two instances were very ill from the time of the previous menstruation until the time mentioned. In the other four cases the husbands were absent during the previous period, and returned at the stated times. This furnishes strong evidence that coitus hastens the rupture of the vesicles of De Graaf. It is generally conceded that the aptitude for intercourse in pregnant women is decidedly diminished; in fact, in some women the instinct develops (temporarily) into disgust. At all events, "it is certain that intercourse is *not* normal in the female during the greater part of the period of utero-gestation." (Flint's "Physiology," p. 888.) In each of the nine cases of abortion above referred to, the sexual instinct was highly developed, and pregnancy, to use the expression of one patient, "rather increased the desire and satisfaction." In such cases, there is reason to believe the ovary tract is readily congested from previous excesses. Another patient informed me that "she knew the very moment when the miscarriage commenced;" she "felt" (after a violent intercourse on her part) "as if something had given way." Thus the history in each case was so complete as to admit of no doubt as to the real cause of premature expulsion of the ovum.

As long ago as 1797, Buffon ("Natural History," vol. iii. p. 203), in following up the researches of De Graaf, said: "We must conclude that the most abandoned women will be the least fruitful, because they emit that liquor which ought to remain in the matrix for the formation of the fœtus. Thus we see why common prostitutes seldom have children, and why women in hot countries, where they have stronger desires than in the cold, are much less fertile." The subject is, therefore, by no means new; but the fact should not be overlooked, as it is, that erections of the uterus, induced by inordinate intercourse, is a positive cause of abortion.

*Experiment.*—In the autumn of 1879 I secured two bitches, in rut at the same time, and allowed two dogs to enter the room, where they were closely watched. After one connection, I took the males out. On the following day four males were admitted, and, after the usual quarrel, all were gratified and withdrawn. On the third and fourth days the females received each a male, and on the fifth one of the two refused its mate in angry tones. The external genitals were, in each instance, red and swollen, and the animals displayed considerable languor. At the end of three days (the eighth after confinement) one of the animals died, and the other gave birth to five undeveloped pups on the eleventh day. The generative tract of the former was in a state of intense venous congestion, and contained some blood, mucus, and a mass of gelatinous material, unmistakably the elements of conception. The living animal escaped, through neglect, and since that time I have not had an opportunity to repeat the experiment. I might add, in the case of the animal that died, that I forced the last connection by holding its feet *in situ* for the male, until she was sufficiently passionate to hold her own. I am sure these experiments can be repeated; and they are instructive in that they tend to prove the disastrous effects of excessive coition.

A bit of conclusive testimony regarding abortion, as the result of uterine erections, may here be quoted from Leishman's work on midwifery, p. 369. Says Dr. Dewees, "very sick women rarely miscarry." Therefore, "we may feel inclined to share the general impression, that sickness is a safeguard, and probably keeps down morbid irritability or rigidity of the uterine fibre."

The final question now presents itself: To WHAT EXTENT MAY THE SEXUAL INSTINCT BE INDULGED, IN THE FEMALE, WITHOUT POSITIVE INJURY? The fact that the constitutions and temperaments of females differ in such varying degrees, precludes anything like definite conclusions in the matter; but the contrast is so striking between cases where orgasm is the inevitable result of each congress, and where it (orgasm) is intermittent, that we are constrained to believe there must be a limit within the range of health. Flint, as above quoted, says: "Intercourse is not normal during the greater part of utero-gestation." Leishman ("System of Midwifery," p. 182), says: "Among Jews the sexes are separate during menstruation and for seven clear days thereafter. This protracted abstention from sexual intercourse may be admitted as a possible cause of the undoubted vitality of the Jewish race;" and in connection with these data, the nine cases of abortion referred to, point to the fact that the sexual instinct can be and is not infrequently sadly abused.

The nearest approach to a law on this subject is the opinion enunciated by Martin Luther. In his mother tongue it is thus poetically expressed:

> "In der Woche zwier
> Macht im Jahr ein hundert vier
> Schadet weder mir nooh dir."

To say the least this is a pretty safe guide; but, I believe, even this might prove excessive in the cases of many women. The careful testimony of physicians, for some time to come, can alone determine how far into pregnancy, and to what extent, the sexual instinct can be indulged with safety; but in the unimpregnated condition, when we discover any such effects as local inflammations (consult Reynolds, vol. iii.), displacements (Thomas), dysmenorrhœa (Thomas), inveterate dyspepsia (Reynolds, vol. iii.), menorrhagia (Reynolds, vol. iii.), gastrodynia (Reynolds, vol. iii.), ovarian neuralgia, "neurasthenia," and frequent abortion, we may find, in many instances, the real source of irritation to be abuse of the sexual instinct, when the remedy will at once suggest itself. Further investigation in this connection is "a thing devoutly to be wished," for continuous congestion of the uterus and its appendages,

from violation of the province of coition, must be highly favorable to pathological conditions; and it is certain that women who continue these excesses are soon debilitated, and become fit subjects for the perilous diseases of "the sex."

## FIVE CASES OF MEMBRANOUS DYSMENORRHŒA CURED BY MERCURY.

By ROBERT ORMSBY, M.D.,
NEW YORK.

It is rather a singular fact that mercury has not been recommended before for the above pathological condition, and I am sure, in the light of modern research, when we have been enabled to see the hyperplastic element in the deciduous membrane of the uterus so pathologically affected, many readers will wonder that, rightly or wrongly, mercury, considering its efficacy in all forms of acute or chronic hyperplasia, should not have been thought of. At the same time, I cannot say that the use of mercury by me was caused by any argument *à priori*, but was simply enough discovered through an accident of a rather unpleasant character, and as follows:

Case I.—A lady (married five years and without children) called at my office, complaining of painful menstruation, which, on examination, I found to be due to the throwing off of a deciduous membrane every month, large shreds and flakes accompanying the flow each time. On further examination, I found the os somewhat constricted, and, to remove all elements of chance from the case, I proceeded slowly to dilate the neck between the time she called upon me and the next menstrual epoch. When within a few days of her expected menstruation, I inserted a sponge-tent of medium size for the purpose of still further and more rapid dilatation. This proceeding was unfortunately followed by metritis and some peritonitis, for which I prescribed the almost classical calomel and opium, as follows:

℞. Ext. opii..... gr. vi.
Hydrargyri chloridi mitis..... gr. xii.

To be divided into twelve pills, and one pill to be taken every four hours; and as her menstrual period had about arrived, I ordered half an ounce of liquor ammonia acetatis every two hours. This last remedy I had frequently used in England and here for the dysmenorrhœa. By a mistake her husband reversed the directions, and, having mixed up the hours of the mixture with the number of the pills to be taken, he gave his wife two pills every two hours. He appeared to have some firm conviction in his own mind that pills were by far the best way of administering medicine, for he gave her the pills most unremittingly, and even went to the trouble of getting them made up again before I called. The result may be imagined. When I called again, about twenty-four hours after, the woman had about twenty-four grains of calomel in her system, and was just as if she had been made of wet paper. He had set up ptyalism with a vengeance, *but her menstrual flow had been started without pain in the interval, and no shreds or traces of a deciduous membrane could be found.* My readers may be sure I stopped the calomel very quickly, ordering the opium to be continued, and giving chlorate of potash. It is now five years since this occurred, and she has had no dysmenorrhœa since.

I was wise enough to accept this hint, and have since tried the remedy upon the following cases, and submit them with all becoming modesty to critical analysis and the test of time.

Case II.—Mrs. F——. Membranous dysmenorrhœa. Gave no treatment till within three days of her expected menstruation, and then gave half a grain of calomel and half a grain of opium three times daily. Menstruation very much improved; a few shreds and very little pain. Told her to come and see me a few days before her next menstruation, which she did. I gave her one grain of calomel and half a grain of extract of opium every four hours. In two days her gums were slightly sore. Told her to take one pill twice a day. Her menstruation appeared next day painlessly, and has been painless ever since, a little over four years.

Case III.—Mrs. P——, married, no children. Gave her, three days before her menstruation, one grain of calomel and half a grain of extract of opium. Gums slightly tender in two days. Instructed her to take one pill twice a day. Her menstruation did not appear next day, as we expected. Told her to take on that day three pills, and on the next day her menstruation appeared painlessly—three years ago, and no recurrence of the pain.

Case IV.—Mrs. H——, sister-in-law of the above; brought from Auburn to be treated; married, no children. This lady did not believe that anything could be done for her relief, as she had tried doctors in all directions. At her last menstruation her husband and relatives despaired of her recovery. Treated her in the same manner as her sister-in-law, and produced as happy a face as ever rewarded a doctor, for, as she said, it was the only time in nine years she had had a painless menstruation. I kept this lady in the city several months to verify my treatment, and repeated it the succeeding month; again no pain. The third month I left to itself, and her menstruation came on painlessly, and has since—that is eighteen months.

Case V.—Mrs. F——. Treatment same as before for one month only. Touched her gums slightly, and kept them so till her menstruation appeared, painlessly as usual. I saw this lady to-day, and her menstruation is on, without any warning, even.

I have never seen this treatment fail, and that its effects are permanent is remarkable; but as there is so much habit in this question of painful menstruation, and as I most decidedly interrupt it, for one month certainly, I think is an almost sufficient explanation. The only thing I would recommend is that the mercury should be pushed to the verge of safety, for I think the modification in the pathological processes occurring in the decidua will be in direct ratio with the impression made on the system. I have not used any form of mercury but the calomel. This at first was the result of chance, but has been since a matter of election, as I think that it is the best form for producing rapid effects with little irritation.

---

Prof. Charcot is not so familiar with the English language as with the nervous system. At the meeting of the International Medical Congress several English and foreign doctors were discussing the style of apparel most suitable for a reception which was to come off that evening. Prof. Charcot quietly observed, "As for me, I shall go in my night-dress."—*Medical and Surgical Reporter.*

# Progress of Medical Science.

NASCENT IODIDE OF SILVER IN THE TREATMENT OF CONJUNCTIVITIS.—According to Sédan (*Recueil d'Ophthalmologie*, May, 1881). M. Brame. of Tours, was among the first to advocate the use of iodide of silver in conjunctivitis. Dr. S. instituted a series of observations, with this remedy, in Algeria, where cases of chronic conjunctivitis are very numerous, and found it decidedly efficacious both as a prophylactic and in the cure of acute and chronic cases.

Two solutions are requisite for the manufacture of the nascent iodide. One of these is a solution of the iodide of potassium, 3 grm. and 32 ctgr. in 10 grm. of distilled water. The other solution is composed of nitrate of silver, 3 grm. and 56 ctgr. in 10 grm. of distilled water. Both solutions are preserved in bottles made of colored glass. The nascent iodide of silver is prepared by dipping separate glass rods into either solution, withdrawing a drop of each and subsequently mingling them on a piece of porcelain. The resulting precipitate of nascent iodide is placed upon the erected lower lid and thence allowed to diffuse itself over the entire conjunctiva. The iodide thus prepared dissolves very slowly in the ocular fluids, and produces much protracted pain. This inconvenience may be obviated by the employment of glycerine as the menstruum. The border of the lids should be anointed with vaseline to prevent them from becoming adherent. Dr. Sédan had constant, rapid, perfect, and permanent results in more than three hundred cases subjected to the treatment in question. He states that a single application will often cure simple cases, while in ninety-two out of one hundred cases, selected at random, less than four applications were necessary to effect a cure.

CALCAREOUS DEGENERATION OF THE MEMBRANA TYMPANI.—Dr. Cineselli (*Il Morgagni*, March, 1881) has investigated the calcareous degeneration of the membrana tympani with reference to its agency in the production of senile deafness. On comparing the ear-drums of a man sixty-five years of age with that of a man twenty-three years of age, he noticed that the former was dotted, chiefly at its centre, with finely granular matter, while the latter had no trace of such an appearance. The solubility of this granular deposit in acids, with effervescence, established its calcareous nature. Dr. Cineselli was led, by observations upon thirty-five individuals, to the following conclusions: the calcareous degeneration of the membrana tympani begins between the thirtieth and thirty-fifth year, and, progressing uninterruptedly, completely incrusts the surface of the drum by the sixty-fifth or seventieth year. Occasionally the calcareous degeneration involves the radiating fibres of the drum, and even of the cartilage, which corresponds to the handle of the *malleus*, in which the central radiating fibres of the drum terminate. Dr. C. is of the opinion that the degeneration in question produces the deafness of old age by diminishing the rapidity and the amplitude of the membrana tympani's vibrations.—*Revue Mensuelle de Laryngologie, d'Otologie, et de Rhinologie*, June 1, 1881.

TREATMENT OF HERNIAS OF LONG STANDING.—The following conclusions are reached by M. Thiry, in a paper on the above subject, presented by him to the Royal Belgian Academy of Medicine: (1.) Old hernias of large extent, constituting a variety of eventration, are susceptible of reduction in most cases. (2.) The large volume of a hernia is never a contra-indication to its reduction, although it necessitates the adoption of certain precautions, and the employment of considerable time. (3.) The diminution in the capacity of the abdominal cavity, in old hernias, is never antagonistic to a slow, methodical, and progressive taxis. (4.) By slowly re-entering the abdominal cavity, the extended parts gradually resume their former places. (5.) The best method of reduction is the "compressing taxis," which consists in only restoring organs to their natural position after they have been relieved, by pressure, of any vascular engorgement. Those organs which effected an exit last should be first replaced. (6.) In this variety of hernia, an elastic truss, adapted to the gradually decreasing size of the tumor, should be attached to an abdominal belt. (7.) When the hernia has been completely reduced, the projecting knob of the truss, with properly shaped convexity, should penetrate the ring and adapt itself to its dimensions.—*Bulletin de L'Académie Royale de Médecine de Belgique*, vol. xv., No. 6.

USE OF PILOCARPINE IN DIPHTHERIA.—Dr. J. Gerard's most enthusiastic recommendation of pilocarpine in diphtheria would carry deeper conviction with it did it not bear evidences of too hasty generalization. The author treated only one case of malignant diphtheria in which the patient seemed moribund in spite of the employment of the ordinary remedies, with the following mixture:

| | |
|---|---|
| ℞. Pilocarpine muriat..... | .05 |
| Pepsin extractive..... ..... | 1. |
| Aquæ destil..... | 150. |
| Acid hydrochloric..... | gtt. iij. |

One-third of the mixture was at first given, and all the physiological effects of the pilocarpine having been speedily produced, violent emesis occurred (within eight minutes), by which the false membranes were expelled. Cyanosis then disappeared and the respiration became normal. The same quantity of pilocarpine having been administered hourly, the child was considered out of danger after twenty-four hours.

M. Sueboullet (*Journal des Sciences Médic. de Louvain*) presented to the medical society of the hospitals a case in which the hypodermic administration of pilocarpine seemed to greatly favor expulsion of the pseudo-membranes by the physiological hypersecretion of saliva and mucus it induced. Recourse having been had, in a desperate case of malignant diphtheria, in which asphyxia seemed eminent, to pilocarpine, two injections, each containing 5 milligr. of the nitrate, were employed in twenty-four hours. The resulting salivation was believed to hasten the expulsion of the membranes. On the two succeeding days three injections of .015 each, were exhibited, after which the remedy was discontinued. On the third day convalescence was begun, and a complete recovery made by the twentieth day.

Professor Giulio Lepodi-Chioti (*ibid.*) publishes his personal observations made in the treatment of diphtheria with pilocarpine, by which he is led to the conclusion that the drug hastens the detachment of the false membranes and abbreviates the course of the disease. He also maintains that the abundant perspiration acts as a powerful emunctory agent and eliminates the virus of the disease from the blood.

The remedy was administered hypodermically and by the rectum. Small doses must be first employed, owing to the susceptibility of many persons to the action of pilocarpine.

*Le Lyon Médicale* publishes the case of a child six and one-half years old, occurring in the practice of Dr. Cassin, of Avignon, in which similar fortunate results attended the use of pilocarpine in diphtheria. The formula employed was as follows:

| | |
|---|---|
| ℞. Pilocarpine muriat..... | .01 |
| Pepsin ..... | .02 |
| Acid hydrochloric ..... | gtt. j. |
| Aquæ destil..... | 120 grm. |

One dessertspoonful was given hourly, for two days. On the fourth day only four doses were exhibited and the remedy then suspended, convalescence being established.—*Archives Médicales Belges*, June, 1881.

Professor Prentiss (*Philadelphia Medical Times*, August 13, 1881), referring to the published cases of Guttman, Lax, and Wendt, says that, in the question under consideration, the preponderance of evidence seems to be in favor of pilocarpine. His own experience with the drug corroborates this view. He prefers, however, the hypodermic mode of administration, using one-sixth of a grain for a dose in adults. Children readily take the drug in the form of powder. Hydrochloric acid solutions he thinks are unnecessary, because they afford no special advantage over simpler ways of giving the medicine.

Bromine Eruption in a Nursling.—At a recent medical meeting in Vienna, Kaposi exhibited an infant, nine months old, suffering from an eruption of the following description: both cheeks were the seat of numerous hard, infiltrated, acinose patches, each as large as a dollar, while the surface was perforated by sharply cut holes, through which pus exuded. There were also brownish red tubercles as large as peas, scattered over the face, and tense bullæ, similar to those of varicella, on the ears. Numerous tubercles, some the size of a bean, were met with on the nates and thighs. The mother stated that the eruption had made its appearance two weeks previously and had spread rapidly. Kaposi at once recognized the case as one of intense bromine acne; but, upon asking the mother for how long a time and in what amount the infant had taken bromide of potassium, she said that it had received none at all. It was elicited, however, that the mother, who was suffering from some nervous affection, had taken 120 grm. of bromide of potassium in a period of two months, but, what was most remarkable, had discontinued the use of the drug two weeks before the first appearance of the eruption. In the way of treatment Kaposi recommends emplastrum hydrargyri, which promotes a rapid absorption of the infiltration, and thus prevents scarring. (The unguent. hydrarg. [Germ. Pharm.], it need hardly be stated, is quite a different preparation from ung. hydrarg., U. S. Ph.—Rep.).—*Allgemeine med. Central-Zeitung*, August 17, 1881.

An Enormous Dose of Pilocarpia.—In the *Wiener medicinische Wochenschrift*, August 27, 1881, Sziklai records a case of glaucoma, which was cured by sclerotomy and the subsequent hypodermic injection of a single dose of the muriate of pilocarpia (2 degr.). The patient was first seen in 1879. He was then completely blind. The eyes were as hard as stone, the pupils dilated *ad maximum*, and the vitreous in each case so obscured as to prevent any view of the retina or optic papilla. Sziklai then performed sclerotomy, and upon making a second visit, three days later, prescribed 4 ctgr. of pilocarpia in 2 grm. of water, of which solution he injected 1 grm. at 7 P.M. The needle had hardly been withdrawn from the skin before saliva began to dribble from the patient's mouth. This was very soon followed by diaphoresis, and later by vomiting, diarrhœa, and diuresis. In the course of the night an enormous amount of fluid was excreted in this way. At the same time the patient complained of tugging pains in the eyes. Next morning, on removing the bandages, the pupils were found extremely contracted and the patient saw very well. The excessive excretions had almost wholly subsided, but the patient was very much prostrated. On examining into the circumstances more closely, it was found that the apothecary had, by mistake, made up a solution of 40 ctgr. (gr. vj.) in 2 grm. (ʒ j.) of water. At the time of the publication, two years after the occurrence, the patient's sight continued to be very good.

Spontaneous Rupture of the Stomach.—Chiari and Lantschner each report a case of this kind. Chiari's case concerned a fifty-three years old woman, who died a few hours after admission into the hospital, the symptoms consisting only of several attacks of vomiting and of intense pain in the belly. On post-mortem examination the curvature of the greatly dilated stomach was found very much shortened by numerous cicatrices, the pylorus being thereby sharply bent on itself, although still permeable. A longitudinal rupture was present in the most extensive cicatrix, extending 3 ctm. on either side beyond the limits of the latter. The laceration involved the mucous membrane, the muscular strata, the peritoneum in the region of the scar, and also the dense adhesions which had formed between the peritoneal surface of the stomach and the peritoneum of the omentum, which had constituted the floor of the ulcer. There were also two smaller lacerations in the vicinity, affecting only the mucous membrane. The margins of the rents were free from any signs of peptic arrosion, so that Chiari concludes that the case was, in part, at least, one of spontaneous gastrorrhexis. A very extensive subperitoneal, mediastinal, and subcutaneous emphysema gradually developed after death. Lantschner's patient was a lady, seventy years of age, who had been affected for forty-five years with an umbilical hernia, which had attained the size of a large gourd. After having taken a walk she complained of great thirst, and subsequently had nausea and vomiting. While retching, the patient and those at the bedside heard a loud report, which was succeeded by collapse, death setting in about thirteen hours later. On post-mortem, the hernial sac, consisting of peritoneum, was found to contain the small intestines, with the pyloric end of the stomach, the coils of the former being partly matted together by adhesions, partly constricted by bands of adventitious connective tissue running from the intestine and mesentery to the thickened hernial sac. Along the posterior wall of the stomach, involving all the coats of the organ, there was a rent several centimetres long, through which particles of food had passed into the peritoneal cavity. In other respects the walls of the stomach were perfectly healthy.—*Allgemeine med. Central-Zeitung*, July 27, 1881.

PUBLISHED BY

WM. WOOD & CO., No. 27 Great Jones St., N. Y.

New York, November 26, 1881.

## THE QUESTION OF MALPRACTICE IN THE CASE OF THE LATE PRESIDENT GARFIELD.

ALTHOUGH so much has been said concerning the surgical and pathological aspects of the case of the late President Garfield, the subject is likely, in view of recent developments in the Guiteau trial, to be kept before the public and profession for more extended discussion. Although Mr. Scoville has more or less directly disclaimed malpractice as one of the lines of the defence, yet there are several reasons which make it not improbable that it may be taken up later in the trial.

At present there is no other way of accounting for the detailed manner in which the several points bearing upon diagnosis, treatment, and mortality of the wound were brought out. It would be strange, indeed, in view of all that has been said *pro* and *con* concerning the surgical management of the case, that the counsel for Guiteau should not gather many points supporting such a plea. Whatever may be the course pursued or the line of argument adopted, there will doubtless be ample opportunity for sifting positive statements from mere suppositions, and of bringing to the test of actual demonstration the theories of such as have so freely and so persistently criticised the actions of the gentlemen in attendance upon the patient.

If the plea of malpractice is offered, the principal point to establish will be whether or no the wound was essentially a mortal one. All other considerations, bearing upon diagnosis, treatment, and precise mode of death, will be, obviously, of secondary importance. While the majority of the profession agree that the disastrous result of the case was inevitable, there are not a few medical men who maintain an opposite view. It must be admitted that there is room for an honest difference of opinion, not only regarding the mortality of the wound *per se*, but as to measures which might have been adopted to avert the issue. Many of these views on one side or the other of the question have been quite freely ventilated, not only in the medical journals, but in the daily press, and the end is apparently not yet. As a contribution to the particular part of the subject under consideration, there appears in the current number of the *North American Review* * a series of articles on the surgical treatment of President Garfield, by several distinguished members of our profession.

These authors, although viewing the case from different aspects, give becoming prominence to the pivotal point in the discussion which refers to the actual mortality of the wound.

Three of the gentlemen in question, Drs. Marion Sims, John Ashhurst, Jr., and Dr. John T. Hodgen, are in accord regarding the affirmative of this proposition, while, as might have been anticipated in view of the wide notoriety of his views, Dr. Hammond takes the negative side. The latter gentleman, being the advocate of the minority, quite appropriately heads the list of writers. Without wishing to detract in any way from the intrinsic merits of the article, it is quite safe, from a perfectly impartial standpoint, to say that the anticipations which were with good reason entertained by many regarding the strength of his arguments and the value of his conclusions, will hardly be realized. The distinguished author takes the ground that the wound of the vertebra was not necessarily a mortal one, that the pus-sac connected with the fractured ribs was the sole cause of the septicæmia, and that death was probably due to heart-thrombus.

In support of the first proposition, a few quotations are made from surgical authorities to show that patients may recover after gunshot wounds of the vertebra. Exceptional as these cases are known to be, there does not appear to be any attempt on the part of the author of the article to prove their similarity in any essential particular with the case of the late President. In view of these insufficient data, it will be a matter of surprise to many that the positive assertion should be risked by him that there was not a single feature, or combination of features, which rendered death inevitable from the wound in the vertebra. As a somewhat astonishing offset to this claim, the pus-sinus is charged solely with causing blood-poisoning, and then quite plausibly blame is thrown upon the attending surgeons for not preventing such a condition of things by earlier and more thorough exploration of the wound. There is hardly a doubt that such an examination of the wound as would be necessary to detect and remove fragments of broken

* The Surgical Treatment of President Garfield. By William A. Hammond, M.D., J. Marion Sims, M.D., LL.D., John Ashhurst, Jr., M.D., and John T. Hodgen, M.D., LL.D. North American Review, Dec., 1881.

rib, might have prevented the formation of the pus-sac, but the particular reasons why such was not done can possibly never be appreciated by any save those who were caring for the case at the time. Allowing for all circumstances that militated against the procedure, there is no questioning, on general principles, the soundness of the practice. Its importance as a plan of treatment is, quite naturally, very much overrated, in connection with the assumption that these fragments caused the burrowing of the pus, and that the pus-sinus was the cause of the septicæmia. It is, however, acknowledged by every one, save this author, that the principal source of septic infection was the wound of the lumbar vertebra. Why the consideration of the latter is ignored, even as an ordinary factor in the final result, can seemingly be explained only on the supposition that the theory of the non-mortal character of said wound would otherwise be quite untenable.

Every one will agree with the author that the mistake in diagnosis was deplorable, but will hardly be ready to believe that any means of more thorough exploration, as advocated by him, would have prevented it. It is quite true that by enlarging the wound the fragments of rib might have been discovered, but it requires something more than a mere assertion to prove that the wound of the lumbar vertebra could be reached by any reasonable exploration (either with the finger or probe), the wound of entrance in the integument being nearly five inches from that in the body of the vertebra. Nor does it appear plain, even if such an examination were possible, how the "approximate location" of the ball could have been anything more than guesswork.

The criticisms regarding the plan of treatment adopted are scarcely becoming in one who never saw the case, and who, unfortunately perhaps for the patient, never had an opportunity of taking into account attending circumstances. And here we come back to the error of diagnosis regarding liver wound, which necessitated a fear (groundless, as now proven) of peritonitis. It is claimed by Dr. Hammond that in consequence of this erroneous hypothesis the patient was subjected to a rigorous antiphlogistic treatment, doubtless meaning the small doses of morphia given to quiet pain. It is quite as difficult to understand why this should result disastrously as that the liability to the occurrence of pyæmia should be increased thereby. It is not easy to understand why the alarming weakness during the first ten hours was occasioned by any excessive and uncontrolled hemorrhage. Certainly none such is reported to have occurred, at least none that could have been controlled by the surgeon. The internal hemorrhage, which doubtless occurred from the injured splenic artery, was obviously beyond reach.

It is hardly necessary to say at this late day that the President suffered from septicæmia, that possibly the final rupture of the traumatic aneurism was caused by his ill-nourished condition, and that death was the result of internal hemorrhage; but our author makes a somewhat startling departure by claiming the possibility of the bursting of the sac by the injection of the embalmer, and that death probably was due directly to the formation of a heart-thrombus, said thrombus having been washed out of the heart also by the injection. As a simple theory it is strikingly ingenious, but as a tangible proposition markedly absurd.

Strangely enough, he maintains that there is no well-supported evidence that the splenic artery was touched by the ball. But this statement will hardly be considered as offsetting the assertions of gentlemen who studied the specimens at the time of the autopsy, and, subsequently, who discovered the opening directly in the track of the ball, and who were able to account for the injury to the walls of the artery in no other way. The question as to whether the aneurism was formed immediately after the infliction of the wound or subsequently, can never be intelligently discussed save by those who have actually seen the specimens.

We have reviewed at some length the statements and opinions of this writer, for the reason that they are generally supposed to represent the strong side of criticism as to the proper management of the President's case. That they fall far short of proving that any really essentially different method of treatment than that adopted would have resulted more favorably is, fortunately for the profession, quite apparent. He does not even claim that the ball could have been found, much less extracted; that any system of drainage for the wound of the vertebra could have been established, thus removing the principal if not the sole cause of the septicæmia, and thus possibly counteracting that general depraved condition of system which caused the rupture of the aneurism.

Contrariwise, the other contributors to the symposium in the *Review* frankly acknowledge that the wound was essentially a mortal one, that the error of diagnosis was, under the circumstances, unavoidable, that the treatment was in accordance with accepted principles in surgery, and that, in reality, nothing more could have been done to have prolonged the life of the lamented sufferer.

It may not be out of place to refer, in this connection, to a communication upon the same subject, which will appear in our next, from a distinguished surgeon criticising the case from other standpoints, more especially such as refer to the finding and extraction of balls in what are generally believed to be inaccessible parts of the body.

### DOES VACCINATION PROTECT?

NOT long ago an International Anti-Vaccination Congress was held in Europe. Few of the delegates were medical men, and none, we believe, had any scientific eminence. The proceedings, therefore, would not deserve notice, but for the fact that by reason of the presence of certain flabby-minded counts and barons, and by the wide telegraphing of certain most audacious "conclusions," much attention was attracted.

Two prominent dailies of this city have lately published editorial comments upon the congress. The good faith and intelligence of the anti-vaccinationists is assumed without question, and the doubt is expressed whether, after all, vaccination is not a mistake, and finally the query is put whether there is anything whatever certain in medical science.

It is becoming somewhat tiresome to have to reiterate the truths about vaccination. And it will sometimes occur to us that the best way after all would be to leave the question alone, and let the people find out the facts for themselves. Why should the doctor worry himself? If the people do not and will not believe in vaccination, why not drop our quills, and, having vaccinated ourselves and families, let the disease work away in its old-fashioned eighteenth century style. In 1721, one-half of the city of Boston lay sick with the small-pox. Would not the return of such a visitation be better than any pamphlets or statistics?

But both humanity and a pride in our profession forbid that anti-vivisection arguments should go unnoticed, when popular ignorance is plainly being imposed upon by them.

It should be understood, therefore, in the first place, that there is no one thing upon which the whole medical profession more unanimously agree than that vaccination affords a protection against small-pox.

We present here a very few of the facts and figures upon which this universal agreement is based. It should be remembered, however, that aside from statistical proof, nearly every physician, at some time during his life, gets personal evidence of the efficacy of Jenner's discovery.

Previous to the introduction of vaccination, the annual mortality from small-pox throughout Europe was about three thousand to every million inhabitants. During the forty years subsequent, the mortality from the same cause was reduced in Sweden to 158 per million; in Westphalia to 114; in Bohemia, Moravia, and Austrian-Silesia, to about 200; in Copenhagen to 286; in Berlin to 176; in England to 200.

In 1853, the Epidemiological Society received two thousand letters from medical men affirming their belief, from personal experience, in the protective power of vaccination. Dr. Simon obtained similar answers from five hundred and forty eminent English and foreign physicians out of five hundred and forty-two to whom letters were addressed.

One observer, Marshall, has shown that among 757 persons exposed to small-pox, 231 had been vaccinated, and of these latter only 27 took the disease. All the remainder, except seven, were infected.

In 1871, an anti-vaccination excitement was fomented in England, and Parliament undertook to investigate the question. A large committee was appointed and testimony taken from every quarter. The result was an overwhelming refutation of the points claimed by the anti-vaccinationists.

In the Franco-Prussian war, an epidemic of small-pox arose among the unvaccinated inhabitants of Brittany. It spread among the French soldiers and destroyed 23,000 of them. The Prussian army, which was frequently and extensively exposed, and was larger than the French, lost only about 250 persons by the disease. The Prussian army was thoroughly vaccinated, the French was not. In the whole Prussian army for twenty years, though often exposed, only four fatal cases of small-pox occurred among the revaccinated.

The conclusions to be drawn from such figures as the above are affirmed by every health board in the country and Europe, and corroborated by the personal experience of all medical men who have a wide acquaintance with the disease. There is not, we venture to say, a small-pox hospital in the civilized world where the belief in the protective power of vaccination does not exist. The most active champions of vaccination, from Jenner, eighty years ago, to Marson at the present day, have been persons who have had the widest practical knowledge of the disease. It is the closet philanthropists, who sit in their houses and study figures, who decry vaccination.

In our own city of New York, the most positive evidence of the protective power of vaccination has been obtained almost daily by the Health Board.

We published only a few weeks ago some facts regarding the small-pox at Pittsburgh, which would alone be quite sufficient to justify vaccination.

As regards the dangers of the method, they are inconceivably trivial when compared with the danger from small-pox. In one year of the eighteenth century this disease destroyed one-tenth of the population of France. In fifty years, one-third of all the children under ten died from the same cause which also during twenty years killed one-eleventh of the population of Copenhagen. For every death there were two or three other cases of sickness. Two-thirds of the pauper blind in England were made so by small-pox.

Such things are impossible now, in the opinion of the entire medical profession; but a return to them would be easy if it adopted the views of the anti-vaccinationists.

There are a few things which have to be borne in mind when arguing for vaccination:

*First.*—Vaccination is protective only when the virus is good, and has entered and affected the system.

*Second.*—There is a very small number of persons who will take small-pox if exposed, whether they have been vaccinated or not. If vaccinated, however, most of these will have the disease less severely.

*Third.*—Vaccination protects in most cases only for a certain period of years, and revaccination is necessary.

*Fourth.*—Vaccine lymph may possibly deteriorate after passing through the human system many times. This deterioration of humanized lymph has probably taken place in England, and perhaps elsewhere in Europe.

*Fifth.*—Small-pox varies in malignancy with the epidemic. There is no evidence, however, to prove that small-pox is any less malignant now, on the whole, than it was eighty years ago.

The above facts have to be considered in passing judgment upon the so-called statistics of anti-vaccinationists.

---

PROGRESS OF WORK OF THE STATE BOARD OF HEALTH.

THE State Board of Health has forwarded to us a series of circulars and other documents issued within the past six months, by which the progress and activity of its work is, in a measure, indicated.

Since our last notice of the Board, it has been engaged in three important investigations. These are in regard to the hygiene of schools, the prevalence of malaria throughout the State, and the adulterations of food and drugs.

A circular has been drawn up which contains a list of sixty-eight questions regarding the hygiene of public schools. These questions involve the subject of sun-lighting, ventilation, heating, water-supply, site and structure of the school-houses, school-hours and physical health of pupils, the relations of the sexes, and the prevailing complaints and sickness. If answers are given in any fulness to these inquiries, a great deal of most important information will have been obtained. It is certainly the duty of the medical profession, so far as it is called upon, to help the State Board in this investigation.

The same obligation exists in regard to the Board's inquiries into the prevalence of malaria. The circulars upon this subject embody some thirty questions, and are accompanied by a blank sheet upon which diagrams of any particularly malarious region may be drawn.

The investigation into the purity of food and drugs has now been going on for some time, and the State may soon expect some definite reports. The Board has issued, in form for distribution, the law to prevent the adulteration of food and drugs as defined by the last Legislature. It may be useful to the physician to know exactly what is the legal meaning of "adulteration of drugs," and we quote here, therefore, the reading of the law on this point.

A drug is deemed adulterated within the meaning of the act:

"*First.*—If, when sold under or by a name recognized in the United States Pharmacopœia, it differs from the standard of strength, quality, or purity laid down therein.

"*Second.*—If, when sold under or by a name not recognized in the United States Pharmacopœia, but which is found in some other pharmacopœia or other standard work on materia medica, it differs materially from the standard of strength, quality, or purity laid down in such work.

"*Third.*—If its strength or purity fall below the professed standard under which it is sold."

A valuable document has been drawn up embodying in outline the sanitary orders and regulations recommended by the Board for adoption by local sanitary authorities. Under eleven different heads, the various measures to be taken for the preservation of life and health are succinctly and clearly indicated.

By this and other means the State Board seems to be striving to make the work of local sanitary organization as easy as possible.

It is a slow and difficult process to impress upon the people the value of sanitary organization. But there are now indications of unquestionable progress in this direction, thanks to the assiduous efforts of a few enthusiastic workers.

---

GUITEAU'S TRIAL.

AT the present writing the plea of insanity in the case of Guiteau has been formally offered by the counsel for the defence. The points brought out thus far are sufficiently familiar to the profession to need no special reference. The line of argument is well taken, and the various eccentricities and insane freaks are presented with becoming directness. The life history of the assassin is made quite interesting by Mr. Scoville, while his associate counsel, the prisoner himself, varies the proceedings by constant and irrelevant interruptions. The latter are calculated to make their due impression upon the jury, and it is barely possible that their full significance in such a direction is appreciated by the prisoner. Altogether the trial on the alleged plea promises to be an unique and interesting one. In our next issue we hope to review the bearing of some of the points which may in the meantime be brought out.

---

LEPROSY IN MARYLAND.—The *Maryland Medical Journal* reports a case of leprosy occurring in a native of Maryland who had never been beyond the limits of the State. There is no evidence of contagion.

## Reviews and Notices of Books.

THE MEDICAL RECORD VISITING LIST FOR 1882. New York: William Wood & Co.

NOTHING seems to us nearer perfect in the line of visiting lists for the practitioner in his daily rounds than this concise, compact, and elegant little book. Not only is the ruling so arranged that a due record can be kept of a practice averaging from thirty to sixty patients per week, but the prefatory text comprises a most judicious selection of such tables and methods as are likely to be often referred to. It is of convenient pocket size, is elegantly bound, is clearly ruled, contains paper suitable for pen or pencil, and has the approved flap-cover. It well deserves its reputation as a general favorite.

A PRACTICAL TREATISE ON HERNIA. By JOSEPH H. WARREN, M.D., Member American Medical Association, etc. Second and Revised Edition. Boston: James R. Osgood & Co. 1882.

THE present second edition of Dr. Warren's essay on hernia will be found more satisfactory than the first, because it is more essentially a general and practical treatise than, like its predecessor, an enthusiastic advocacy of a single method of operation. Heaton's injection "cure" (?) is, however, still conspicuously pushed to the foreground. But the other methods of treating hernia are, at least, considered with sufficient detail to make the work of real value to the physician. Among the newly added chapters, that on hydrocele and varicocele might, without detriment to the book, have been entirely omitted, as it contains but an inadequate compilation of a highly important subject. Three beautifully executed heliotype plates form a convenient and useful anatomical addition to the book.

A MANUAL OF PRACTICAL NORMAL HISTOLOGY. By T. MITCHELL PRUDDEN, M.D., Director of the Physiological and Pathological Laboratory of the Alumni Association of the College of Physicians and Surgeons, New York, etc. New York: G. P. Putnam's Sons. 1881.

AT the present rate of increase in the preparation of works on histology, a medical Vennor might readily compute the probable time which must still elapse before every teacher of this branch of medicine will have written at least two books on the subject. The elementary manner in which the little volume before us deals with histology will recommend it to such students only as are studying under an instructor, who may be constantly appealed to for more complete information and fuller details. Doubtless a familiarization with its contents will enable the student to profit more by a systematic laboratory course than would otherwise be the case. Judged from such a point of view, Dr. Prudden's little manual has its *raison d'être*, but apart from that it need scarcely have been written.

A TEXT-BOOK ON PHYSIOLOGY. By M. FOSTER, M.A., M.D, F.R.S., etc. Second American, from the Third and Revised English Edition. With Extensive Notes and Additions. By EDWARD T. REICHERT, M.D., Demonstrator of Experimental Therapeutics, University of Pennsylvania. Philadelphia: H. C. Lea's Son & Co. 1881.

IT is a pleasing sign to observe the appreciation of so thoroughly scientific a work as Foster's "Physiology" by the American student—an appreciation which is amply proven by the fact of the exhaustion of the first American edition within a twelvemonth. In its present shape the work will be found thoroughly up to the times, recent advances in physiology having been duly noticed by the American editor. The only criticism which we have to offer is, that Dr. Reichert insists on substituting the somewhat misleading compound "physiological anatomy" for what is, by common consent, called histology; and further, that the histological details are often so meagre as to seem almost superfluous. The student should either be referred to some more complete manual of histology for even an elementary knowledge of the minute structure of tissues, or else he should have a sufficient array of facts presented, which would make such reference needless.

## Reports of Societies.

### NEW YORK SURGICAL SOCIETY.

*Stated Meeting, October* 11, 1881.

DR. H. B. SANDS, PRESIDENT, IN THE CHAIR.

#### HYPERTROPHY OF THE RIGHT SIDE OF THE NOSE.

DR. LITTLE presented a patient, a woman twenty-five years of age, with the following history: About six or seven yeas ago she noticed for the first time that the right side of her nose was larger than the other. Since that time the deformity had gradually increased, and during the last year its growth had been much more rapid than previously. He had not been able to obtain any evidence that it was of a congenital origin. It was not painful, nor did handling give rise to pain. It had a feel somewhat like a nævus. The question of the propriety of an operation was submitted to the society.

#### TUMOR OF THE LOWER JAW.

Dr. Little also presented a boy ten years of age, who a year ago had a diseased tooth in the lower jaw on the right side, which was followed by a swelling that had gradually increased in size. The tumor had been hard and insensible until within the last three or four days, when it began to be sensitive upon pressure. There had been one or two small openings in it, which had healed. His first opinion was that it was a dentigerous cyst. Dr. Little then referred to a case of dentigerous cyst seen in Burlington, Vt., two years ago, in which he opened the sac and found a portion of a tooth at the bottom. Last year he saw a patient in whom two or three cysts of like character had formed, but no tooth was found. In the present instance the swelling had increased to such an extent as to render it somewhat difficult to open the mouth. He was not fully satisfied of its character, but thought it probable that it was a cyst caused by a diseased tooth. There had been no inflammatory symptoms in the earlier stages.

DR. A. C. POST thought that in the first case the deformity could be relieved by removing a wedge-shaped portion of tissue. It could be done with perfect safety, and probably a free incision would arrest the tendency to further growth.

DR. BRIDDON asked if there was any history of neurosis in the case.

Dr. LITTLE answered that he had not been able to

obtain such a history. Some time ago he had a case of thickening of the upper lip, and he removed a portion of tissue with a favorable result.

Dr. Briddon asked concerning the second case, if it was not unusual for a dentigerous cyst to attain to the size of the tumor in the present case.

Dr. Little remarked that the tumor in the case seen in Burlington occurred in an adult, and probably was not more than half the size seen in the patient exhibited. In that case there was an expansion of the bone, especially its outer layer.

Dr. Schönborn suggested that the tumor was a sarcoma of the jaw.

The President suggested that light might be thrown upon the case by harpooning and examining the tissue with the microscope.

Dr. Markoe thought that the tumor did not have the feel which a dentigerous cyst usually gives. It was irregular in shape, and suggested the opinion which Dr. Schönborn had already given, namely, that it was sarcomatous in character.

Dr. Howe referred to a case which appeared at his clinic at the Bellevue Hospital Medical College. The tumor was hard and smooth, and extended upward and involved part of the upper jaw. There was no fluctuation perceptible at any point. The history of the case seemed to point toward sarcoma. He had some thoughts of removing the tumor with the jaw, but waited for further developments, and on a subsequent day, when the patient appeared, there was fluctuation all through the enlargement, and it was found that the child had had a chill. The softened mass was opened, and it was found to contain nothing but pus. It was doubtful whether the disease originated in the periosteum or in inflamed glands. All that was found at the operation was pus and denuded bone.

### DEFORMITY OF THE HANDS THE RESULT OF CICATRICIAL CONTRACTION FOLLOWING AN EXTENSIVE BURN.

Dr. A. C. Post narrated a case which he illustrated with plaster casts, representing the appearance of the hands of a man twenty-four years of age, who was a native of Kentucky and came under his care during the last summer. About two years ago he was exposed to an explosion of gunpowder, and his hands and forearms were severely burned. The cicatricial contraction which followed the burn had distorted the hands and fingers as represented in the models. On the left hand the little finger was dislocated at the articulation between the first and second phalanges, and bent at an angle a little less than a right angle, perhaps eighty degrees, the first phalanx being drawn back by muscular contraction, and the others bent into the palm. The ring and index fingers, were bent at an obtuse angle by cicatricial bands, and the thumb was drawn toward the little finger by a firm cicatricial band passing transversely across the middle of the hand. There were some cicatricial bands which webbed the fingers together posteriorly. On the other hand, similar cicatricial bands contracted the palm of the hand, adducted the thumb, drew forward the little finger so that its last phalanx was dislocated and bent at a right angle, and immovably fixed. This patient came under his observation in last May, while in attendance at the American Medical Association in Richmond. He was advised to come to New York, where he came, and entered the Presbyterian Hospital on the 2d of last June. On the 6th day of the same month Dr. Post divided the cicatricial bands by multiple incisions, so as to separate the tissues widely, and where the fingers were dislocated he performed exsection of the distal end of the proximal bone of the joint at which the dislocation occurred, and removed about one-fourth of an inch, thus enabling him to bring the fingers into place. The hands were secured by felt splints, stiffened by hoop iron behind; the fingers were separated from each other, and confined in a position opposite to the deformity. On July 30th he performed certain supplementary operations, as the wounds had all healed and there was still considerable contraction across the palm of the hand. He then divided the webs on the posterior part of the hands, cut up the cicatricial bands on the palmar surface into rhomboidal segments, applied lint moistened with carbolized oil, and the wounds healed readily. There was scarcely any suppuration, and the wounds were left six days before the dressings were changed, and when they were removed it was found that a good deal of progress had been made toward healing. The patient left the city on August 24th, and the casts presented represented the greatly improved appearance of the hands at the time that he was discharged from the hospital. He was also getting very good use of the fingers. He was directed to keep the splints adjusted during the night, and to resort to active and passive motion freely during the daytime.

There was one interesting feature in these cases, and that was the condition of the thumb. The distal phalanges of the thumbs were drawn forcibly backward, and entirely by muscular action. There was no cicatricial action behind to aid in producing that deformity. In connection with this case he referred to a case under treatment during last summer. A boy eight or nine years old received a fall by which he fractured the bones of one of his forearms at about the middle. It was a simple fracture, which had united before he had observed him; but a structural change had taken place in the middle of the forearm to such an extent as to cause contraction of the fingers so that they were hooked, and the thumb was drawn across the palm of the hand and almost entirely immovable. Dr. Post made an incision across the commissure of the thumb. Although there was no cicatricial contraction, there was some induration and firm resistance of the tissues, until he reached the tendon of the long extensor of the thumb, which he divided, and then was able to bring the thumb into proper position. He made a longitudinal incision over the entire mass of indurated tissue in the forearm, separated the edges, passed the director under the superficial layer of muscles and divided them, and that gave considerable motion. He was then able, by applying an apparatus, to bring the fingers into a very good position. He had not obtained much motion, but the deformity had been very much diminished. There was some motion in the fingers, which probably would improve, although he did not think that the patient would ever have the full use of the hand.

Dr. Markoe thought the interest in Dr. Post's case was in the fact of the method adopted, namely, open and multiple section. He thought that Dr. Post's cases showed that the method was a safe one, but still the question remained, to what degree was the tendency to contract overcome by the operations.

Dr. Post replied that there was positive advantage in making several small incisions instead of one very large chasm, and the granulations were easily kept down by bandages and the occasional applica-

tion of nitrate of silver. A number of parallel incisions, leaving small spaces to be filled by granulation, answered a much better purpose than one incision making a wide chasm. He had one case in which he had operated more than twenty years ago, and he had been able to follow it ever since. It was a case of extreme contraction; the back of the hand was brought into close contact with the posterior surface of the forearm, and was the result of a burn. In that case there had been no disposition whatever to contract since the completion of the treatment following the operation. The child had grown to be a woman, and she is now able to perform with facility upon a musical instrument. A disposition to contract had not existed in other cases which he had had under observation.

LATERAL DISPLACEMENT OF THE BLADDER.

DR. BRIDDON narrated a case as follows: On the 28th of July he saw a patient, a boy nine years of age, in consultation with a physician, at Whitestone, L. I. The messenger told him that the case was supposed to be one of intestinal impaction, and from what he could gather he was led to conclude that it was probably a case of perityphlitis. The attending physician, on his arrival, told him that he was not certain about the nature of the case; that he was called to see the boy about twelve days previously, and found him suffering from acute pain, located in the right inguinal region, which was so severe in character that it did not readily yield to morphine, used hypodermically and in very large doses. When morphine was omitted the pain was so intense that the cries of the patient could be heard at some distance. During the last five days, however, the pain had shifted from the inguinal region to the epigastrium, and had been accompanied with fever and abdominal tenderness. On examination, it was found that the condition of the patient was very unfavorable. He had sordes upon his gums, teeth, corners of the mouth; his tongue was dry and brown; his pulse could scarcely be felt; his pupils were contracted, and the patient seemed to be almost moribund. His position was the dorsal decubitus, with the right thigh slightly flexed upon the pelvis. There was dulness in the right inguinal region, extending upward as high as the umbilicus, but not passing to the left of the median line. It was easy to detect fluctuation over this space, but there was no perceptible enlargement of the abdomen. On introducing the index finger into the rectum, Dr. Briddon discovered nothing abnormal, and bimanual manipulation brought the finger in the rectum in contact with the fingers of the other hand, placed upon the outside, over the pubis. He passed an aspirating needle into the midst of the region of dulness, about one inch above the centre of Poupart's ligament, and removed a fluid which looked exactly like urine, but which had neither a urinous odor nor taste. It tasted decidedly bitter. He then examined the rectum again, and found nothing more than had been found at the previous examination. The patient had had no trouble whatever in passing urine, and the mother stated that he had passed a tumblerful of water that morning without difficulty. He then made an incision two inches long, parallel with and one inch above Poupart's ligament, the centre of which was over the middle of the ligament. The incision was carried down to the abdominal fascia, which was opened with the finger, and no purulent deposit was found. The external iliac artery was exposed, and could be seen and felt. By making pressure above, he was enabled to force downward the fluctuating tumor, so that it bulged, and could be seen in the incision, and he passed a needle into it and obtained fluid of the same character of that obtained by the aspirator. He then attempted to pass a No. 12 silver catheter, the only one he had with him, and was unable to do so, even after dividing the meatus. It was evident that this collection of fluid was the cause of the pain, and he therefore made an incision into it, passed his finger in and found that it was the laterally distended bladder. The peritoneum was not opened at all. Keeping his finger in the opening in the sac, he sent the doctor for a small catheter, which he succeeded in introducing, and demonstrated that the tumor which he had opened was the bladder. The viscus occupied the right side of the pelvis and inguinal region, and it was evident that the peritoneum had been lifted up by it. He introduced a large-sized drainage-tube into the bladder, stitched it into the abdominal wound and left the child, with considerable misgivings as to the ultimate result. On August 2d he received a letter from the doctor, who stated that the patient was improving; that the temperature was normal; that he suffered but little from pain; that he was taking nourishment freely, and was bright and cheerful. The urine was passing through the wound. On the 23d of August he received a second letter from the doctor, in which it was said that the patient did well until the wound had almost entirely united, when the bladder became distended, and the patient again complained of sharp lancinating pains in the epigastrium, a burning sensation in the penis, and had a frequent desire to urinate, without being able to pass any water. The doctor attempted to pass a soft catheter, but was unable to do so without an anæsthetic. It was then found necessary to dilate the wound, and when this was accomplished by his medical attendant sufficiently to allow a free discharge of urine, the boy was immediately and completely relieved, and since that time it had been necessary to keep the fistulous opening patent by the aid of bougies. What the nature of the pain, in the early history of the case, was, Dr. Briddon was unable to say. There was no dysuria or vesical tenesmus, and the attention of the physician and the parents had not been drawn to the bladder. From the data which he had been able to obtain, he doubted whether the condition of the bladder was the cause of the original pain from which the boy suffered.

DR. A. C. POST thought that if the severe abdominal pains existed when the sinus was closed, and were relieved by opening it and allowing a free escape of urine, it was a fair inference that the retention of urine was the cause of pain.

DR. BRIDDON said that Dr. Post's reasoning was good, but he did not see how a boy could suffer so much pain without at some time directing the attention of those who were about him to the condition of the bladder.

DR. POST referred to a case in which, early in his professional life, he had an opportunity to make a post-mortem examination. The child died with abdominal pain and swelling, and the report was that the urine had passed freely all the time, and yet he found the bladder distended up to the umbilicus, and the so-called free passage of urine had simply been an overflow. The autopsy was interesting, as showing that abdominal pain and swelling, and death, was due to the distention of the bladder from retention of urine. He had seen similar cases oc-

curring in old men. He had also seen an analogous condition of the bowels attended by annoying diarrhœa, abdominal swelling and pain, all dependent upon impaction of the colon. These symptoms had been promptly removed by the use of cathartics and enemata, which completely emptied the bowels.

(To be continued.)

## NEW YORK ACADEMY OF MEDICINE.

*Stated Meeting, November* 3, 1881.

FORDYCE BARKER, M.D., LL.D., PRESIDENT, IN THE CHAIR.

THE Librarian reported that 231 bound volumes, 44 unbound, 888 pamphlets, and 2,049 medical journals had been presented to the Academy since his last report.

Dr. Purple presented three rare books received from Dr. Isaac E. Taylor—rare on account of their age and inability to duplicate them, as well as their intrinsic value.

DR. T. A. MCBRIDE then read a paper on

### THE EARLY DIAGNOSIS OF CHRONIC BRIGHT'S DISEASE.

The author first designed to consider only that form of the disease which began insidiously, progressed slowly, and gave the cirrhotic, granular, or atrophic kidney; but there were certain cases of chronic parenchymatous nephritis, and also certain other cases of chronic diffuse nephritis, which began equally as insidiously, and progressed as slowly as did the form of the disease in which the atrophied kidney was found.

Most of the signs and symptoms of the atrophic kidney were common to the other chronic forms of Bright's disease; but in his paper Dr. McBride studied:

*First.*—Those cases in which the symptoms and signs present were well-marked—cases which had existed for some time, and in which extensive anasarca and œdema had appeared.

*Second.*—The class of cases in which no symptoms appeared until the patient received some injury, or was attacked by some disease, as pneumonia, tonsillitis, etc.

*Third.*—The class of cases in which the disease, in patients heretofore supposed to be healthy, was ushered in with a convulsion, coma, fever, and head symptoms, etc.

*Fourth.*—A series of six cases in which lithæmia terminated in chronic Bright's disease.

Lastly, he called attention to the probable fact that chronic diffuse disease of the kidneys, and of the arteries, was produced most commonly by the circulation and elimination of certain excrementitious material present in the blood, and that fact had its value in making a diagnosis.

The *subjective* symptoms of chronic Bright's disease were: headache (frontal, vertical, occipital), deafness, amblyopia, dyspnœa (spasmodic, Cheyne-Stokes, heart-disease, etc.), dyspepsia, nausea, vomiting, etc.

The *objective* symptoms were: 1st, pallor of the skin and mucous membranes, baldness, gray and dry hair; 2d, dry skin; 3d, permanent pulsating tortuous temporal arteries; 4th, eye of Bright's disease; 5th, subconjunctival œdema; 6th, odor of the breath; 7th, emaciation; 8th, œdema of the legs (present in health); 9th, condition of the urine: odor, frothing, frequency of passing it, quantity in twenty-four hours, specific gravity, color, albumen, tube-casts; 10th, increased arterial tension; 11th, hypertrophy of the heart; 12th, endarteritis chronica; 13th, coma and convulsions.

#### THE URINE.

With reference to the urine, it was a general fact that the longer the disease continued, the greater would be the quantity excreted. Attention had been directed by Dr. Alonzo Clark in 1861, to the fact that the urine was inodorous.

In chronic parenchymatous nephritis the quantity of urine passed in twenty-four hours was usually above the normal, and the greater the quantity the less frequent were the returns to the normal. In chronic diffuse nephritis the quantity of urine was apt to be small at first, then become increased, and then diminished, and perhaps suppressed; but in general the longer the patient lived, the larger the quantity excreted.

Quotations were made from Bartels and Grainger-Stewart, who quoted from Dickinson, to the effect that, in most chronic cases, whether the Bright's disease succeeded an acute attack or was a chronic process primarily, the quantity of urine excreted in twenty-four hours was increased. One should bear in mind, however, the fact, in taking the quantity, that any cause which led to diminution in arterial tension, any cause which led to over-distention of the right side of the heart, might lead to reduction in the quantity of urine to the normal, or even below. A careful examination of the urine with reference to the quantity passed in twenty-four hours, was an important aid in diagnosis.

The *specific gravity* of the urine in chronic parenchymatous nephritis did not differ much from normal—usually from 1020 to 1025; might be as high as 1030 to 1035, or as low as 1005 to 1020.

In chronic diffuse nephritis the specific gravity was regularly below the normal; usually below 1020, frequently 1010 or under.

Numberless observations, almost, had convinced him that, in extreme cases of this variety of kidney disease, although the quantity of urine might be small, the specific gravity could not rise above 1009 or 1011. Here, again, the general statement held good, that the longer the disease existed, the lower would be the specific gravity of the urine; but, in making the estimation in any stage of the disease, it was necessary to consider those causes and conditions which might produce an increase in the specific gravity.

The *presence of albumen* in the urine was next considered, and reference made to tests, with the condition necessary in order to render them reliable. It was also especially important to bear in mind the fact that albumen might be temporarily present in apparent health, and in connection with several diseases. It was frequently found in the urine of patients suffering from lithæmia, although the excretion might have a high specific gravity and be loaded with urates.

Dr. McBride also directed attention to some of the theories offered in explanation of the temporary presence of albumen in the urine in health. If, however, with proper care in testing, he found albumen; if there was a strong hereditary tendency to Bright's disease; if the patient had high arterial tension, perhaps one of the diseases resulting from high tension, or one of the diseases so often associated with Bright's disease; or if there was present a disease to which Bright's disease was often second-

ary, he believed that he was justified in stating that the albumen was a symptom of beginning structural disease of the kidney.

The *presence of casts* in the urine was not so important a symptom as was at one time supposed. It was doubtful whether casts were ever obtained from beyond the down-looping tubes of Henlé, although cast-material might be forced through the loops from the labyrinth of the kidney.

Dr. McBride then directed attention to

INCREASED ARTERIAL TENSION,
